Abstract

This paper is the first to present direct evidence showing how localized knowledge spillovers arise from workers changing jobs within the same local labor market. Using a unique dataset combining Social Security earnings records and balance sheet information for the Veneto region of Italy, I first identify a set of highly productive firms, then show that hiring workers with experience at these firms significantly increases the productivity of other firms. My findings imply that worker flows explain around 10 percent of the productivity gains experienced by incumbent firms when new highly productive firms are added to a local labor market.

Keywords: productivity, agglomeration economies, local knowledge spillovers, linked employer-employee data, labor mobility, instrumental variable. JEL: R10; D24; J31; J60.

1 Introduction

A prominent feature of the economic landscape in many developed countries is the tendency for firms to locate near other firms producing similar products or services. In the United States, for example, biopharmaceutical firms are clustered in New York and Chicago, and a sizeable share of the elevator and escalator industry is concentrated in the area around Bloomington, Indiana. Further, the growth and diffusion of multinational corporations has led to the recent appearance of important industrial clusters in several emerging economies. Firms that originally agglomerated in Silicon Valley and Detroit now have subsidiaries concentrated in Bangalore and Slovakia (Alfaro and Chen, 2014).

Researchers have long speculated that firms in such industrial concentrations may benefit from agglomeration economies, and a growing body of work has been devoted to studying the importance of these economies. Despite the difficulties involved in estimating agglomeration effects, a consensus has emerged that significant productivity advantages of agglomeration exist for many industries (Rosenthal and Strange, 2003; Henderson, 2003; Cingano and Schivardi, 2004; Ellison, Glaeser and Kerr, 2010; Greenstone, Hornbeck and Moretti, 2010; Combes et al., 2012). Disagreement remains, however, over the nature of the microeconomic mechanisms that can account for these advantages (Glaeser and Gottlieb, 2009; Moretti, 2011). This serves as a barrier to understanding differences in productivity across industry clusters and localities, and hinders the design of location-based policies (Glaeser and Gottlieb, 2008; Kline, 2010).

Localized knowledge spillovers are one of the most commonly hypothesized sources of the productivity advantages of agglomeration, alongside the availability of specialized intermediate inputs, the sharing of a common labor pool, and better matching. Nevertheless, if information can easily flow out of firms, the question why the effects of spillovers are localized must be clarified – a point well-made by Combes and Duranton (2006).

This is the first paper to present direct evidence showing how firm-to-firm

labor mobility enhances the productivity of firms located near highly productive firms. In doing so, it lends support to the idea that the strong localized aspect of knowledge spillovers discussed in the agglomeration literature arises – at least in part – from the propensity of workers to change jobs within the same local labor market: knowledge is partly embedded in workers and diffuses when workers move between firms.¹

To fix ideas, I begin by presenting a simple conceptual framework in which some firms are more productive because they possess superior knowledge.² Employees at these firms acquire a proportion of the firm’s internal knowledge – for simplicity, I refer to these employees as ‘knowledgeable’ workers. Other firms can then gain access to this superior knowledge by hiring such workers.

The central empirical goal of the paper is to measure the importance of labor market-based knowledge spillovers. In confronting the non-trivial measurement challenges involved, I take advantage of a unique dataset that combines Social Security earnings records and detailed financial information for firms in Veneto, a region of Italy with many successful industrial clusters. In the empirical analysis, I identify potential high-productivity firms as those that pay a relatively high firm-specific wage premium.³ I show that these high-wage-firms (henceforth, HWFs) have significantly higher total factor productivity (TFP) and value-added than other firms in my sample, suggesting the presence of a firm-specific advantage and thus a point of origin for the transfer of knowledge. For convenience, I refer to these HWFs as ‘good’ firms. Next, I evaluate the extent to which other firms benefit from hiring knowledgeable workers by studying the effect on productivity associated with hiring workers with recent experience at these good firms.

¹Other possibilities include various forms of communication externalities: face-to-face meetings, word-of-mouth communication and direct interactions between skilled workers from different firms (Charlot and Duranton, 2004).

²The superior knowledge could include information about export markets, physical capital, new organizational forms and intermediate inputs.

³This is consistent with many recent models of frictional labor markets (e.g., Christensen et al., 2005), in which higher-productivity firms pay higher wages for equivalent workers. Results are similar when using alternative groupings of firms based on output (controlling for inputs) and value-added.

Given that workers do not move from firm-to-firm on a random basis, my analysis addresses important identification threats. In particular, positive productivity shocks that are correlated with the propensity to hire knowledgeable workers may give rise to an upward bias in the estimated impact of such knowledgeable workers.⁴ To address this potential endogeneity issue, I use well-established control function methods drawn from the productivity literature (Olley and Pakes, 1996; Levinsohn and Petrin, 2003). Doing so, I find that on average recruiting a knowledgeable worker increases the productivity of a non-HWF by between 1.8 and 3 percent.⁵

It is also possible that knowledgeable workers are attracted to join firms that are ‘on the rise,’ (i.e. firms that offer better prospects than the good firms at which these workers are employed) rather than knowledgeable workers moving to firms and causing the increase in productivity. To address this reverse-causality concern, I instrument for the number of knowledgeable workers employed by a non-HWF with the number of good firms in the same industry locally that downsized in the previous year. Following a downsizing event at a good firm, it is more likely that a knowledgeable worker applies for a job at local non-HWFs because she is unemployed and does not want to relocate far away. Put differently, in the scenario captured by the IV approach, the strategic mobility explanation is less likely to play a role.⁶ This is a new approach: the number of downsizing local good firms provides a convincing instrument for a firm input in a production function framework and to date, only past values of the regressors themselves or input prices have been used for instrumentation in the production function literature – see the survey by Eberhardt and Helmers (2010).⁷ Applying this approach, the IV estimates return

⁴Examples of such shocks are process innovations and new managerial techniques.

⁵While this may seem like a large effect, non-good firms are quite small: their median number of employees is 33. Further, as many as 78 percent of non-good firms in a given year do not employ any knowledgeable workers. Hiring one knowledgeable worker therefore implies a significant change for most firms in my data.

⁶While the timing of these moves is arguably exogenous, knowledgeable workers may still decide which new employer to join among the set of non-good firms after being displaced by good firms. However, in small labor markets and specialized industries, workers are likely to have a limited set of alternatives.

⁷As an alternative approach to address the possibility of workers being attracted to join

an economically and statistically significant effect of recruiting knowledgeable workers on the productivity of non-HWFs. The exclusion restriction would be violated and the coefficient on knowledgeable workers biased upwards if there were localized unobservable industry-specific shocks that led good firms to downsize and *positively* affect measured productivity at non-HWFs. An example of such shocks are unobserved shifts in local demand from the products of HWFs to the products of non-HWFs. I obtain data on the level of tradability of goods and I construct an index of industry localization and show reassuring evidence regarding the relevance of such shocks.

Additional evidence supports the main finding that the recruitment of workers with experience at good firms significantly increases the productivity of the non-HWFs hiring them in a causal manner. I observe greater productivity gains in firms hiring workers in *higher-skilled* occupations. The productivity effect of knowledgeable workers is not due to unobserved worker quality,⁸ and it is not associated with recently hired workers in general; placebo regressions show that there is no similar productivity effect for recently hired workers with experience at firms that have lower productivity than the receiving firm.⁹ These results indicate that the estimated effect is not due to better worker-firm matching, or switchers being more productive than stayers in general (regardless of previous employment history). I also rule out the possibility that the results are driven by time-invariant unobservables such as managerial talent.

In the second part of the paper, I evaluate the extent to which labor mobility can explain the productivity advantages of firms located near other highly productive firms. I relate my findings on the effect of firm-to-firm labor mobility to the existing evidence on the productivity advantages of agglomeration,

firms on the rise, I adapt control function methods to proxy for future productivity shocks.

⁸In order to investigate this issue, I obtain a proxy for worker ability using estimates of worker fixed effects from wage equations where both firm and worker effects can be identified.

⁹Also, if a positive and significant relationship between labor mobility and productivity was driven by higher ability workers moving from good firms, then the coefficient on recent hires from firms with productivity lower than the receiving one would be negative and significant, since hiring labor from such firms would cause a decline in the firm's average worker quality and therefore deteriorate its productivity. I find that such coefficient is very small and positive.

focusing on a study by Greenstone, Hornbeck and Moretti (2010, henceforth GHM). Those authors find that, following the opening of a large manufacturing plant, the total factor productivity (TFP) of incumbent plants in the US counties that were able to attract these large plants increased significantly relative to the TFP of incumbent plants in counties that survived a long selection process but narrowly lost the competition. The observed effect on TFP in GHM is larger if incumbent plants are economically close to the large plant – measures of economic links include a dummy indicating belonging to the same industry, and indicators of technological linkages and workers flows at the industry level. Further, this TFP effect increases over time. These facts are consistent with the presence of intellectual externalities that are embodied in workers who move from firm-to-firm. However, data limitations prevented GHM from drawing definitive conclusions regarding the underlying mechanism. Building on their analysis, I am able to evaluate the extent to which worker flows explain the productivity advantages of agglomeration by predicting the change in local productivity following an event analogous to that studied by GHM within the worker mobility framework described above. I find that the change in productivity predicted within this framework is around 10 percent of the overall local productivity change observed after the event.¹⁰

Finally, I show that the local productivity effect attributed to good firms does not appear to be associated with a general increase in the size of the labor market: large productivity gains linked to changes in the number of firms seem to be realized only when the new entrants are good firms. This evidence suggests that the estimated impact does not reflect better worker-firm matching arising from a thicker labor market.

The remainder of this paper is organized as follows: in Section 2, I relate my research to the existing literature. Section 3 first presents a conceptual framework that guides the empirical exercise and then discusses my econometric strategy. In Section 4, I describe the data and present descriptive results.

¹⁰The remaining portion is likely to be explained by other types of knowledge spillovers not based on labor mobility (i.e. various forms of communication externalities) and the availability of specialized intermediate inputs.

The main regression results, in addition to various extensions and robustness checks, are presented in Section 5 and 6. Section 7 concludes.

2 Relation to Previous Research

This paper adds to the growing literature examining productivity advantages through agglomeration, a literature reviewed in Duranton and Puga (2004), Rosenthal and Strange (2004) and Moretti (2011). The research relating most closely to this paper studies the micro-foundations of agglomeration advantages based on knowledge spillovers. In the theoretical analysis by Combes and Duranton (2006), firms clustering in the same locality face a trade-off between the advantages of labor pooling (i.e. access to knowledge carriers) and the costs of labor poaching (i.e. loss of some key employees to competitors along with higher wage bills to retain other key employees).¹¹ In a case study of the British Motor Valley, Henry and Pinch (2000) conclude that

as personnel move, they bring with them knowledge and ideas about how things are done in other firms helping to raise the knowledge throughout the industry...The crucial point is that whilst this process may not change the pecking order within the industry, this ‘churning’ of personnel raises the knowledge base of the industry *as a whole within the region*. The knowledge community is continually reinvigorated and, synonymous with this, so is production within Motor Sport Valley.

In a similar vein, Saxenian (1994) maintains that the geographic proximity of high-tech firms in Silicon Valley is associated with a more efficient flow of new ideas. I contribute to the literature on the micro-foundations of agglomeration advantages by showing direct evidence of productivity gains through

¹¹The study of R&D spillover effects by Bloom, Schankerman and Van Reenen (2013) points out the presence of two countervailing effects: positive technological spillovers and negative business-stealing effects on the product market. The authors provide evidence that although both types of effects operate, technological spillovers quantitatively dominate.

worker flows. My results are consistent with the discussion in Henry and Pinch (2000).

Some research outside the agglomeration literature has also emphasized that firm-to-firm labor mobility may enhance the productivity of firms. Dasgupta (2012) studies a dynamic general equilibrium model with mobility of workers among countries, in which the long-term dynamic learning process plays a crucial role. Workers in the model learn from their managers and knowledge diffusion takes place through labor flows. Other theoretical contributions include the studies by Cooper (2001), Markusen (2001), Glass and Saggi (2002) and Fosfuri, Motta and Rønde (2001). Several convincing firm-level empirical analyses have already been conducted: Poole (2013) finds a positive effect of the share of new workers previously employed by foreign-owned firms on wages paid in domestic firms in Brazil. Balsvik (2011) offers a detailed account of productivity gains linked to worker flows from foreign multinational to domestic firms in Norway. Parrotta and Pozzoli (2012) provide evidence from Denmark regarding the positive impact of the recruitment of knowledge carriers – technicians and highly educated workers recruited from a donor firm – on a firm’s value added; and Stoyanov and Zubanov (2012) show that Danish firms that hired workers from more productive firms become more productive.¹²

My findings are consistent with these recent empirical contributions of Poole (2013), Balsvik (2011), Parrotta and Pozzoli (2012) and Stoyanov and Zubanov (2012) that study worker flows using linked worker-firm data. In terms of the firm-level analysis, which is the focus of the first part of my paper, I build on their research and show evidence of a causal effect of labor mobility on firm productivity using a variety of approaches (IV, control function methods, placebo regressions). Unlike the above authors, who focus exclusively on the relationship between labor mobility and productivity at the firm level, I also seek to shed light on a broader question: to what extent can labor mobility

¹²The related literature also includes Agrawal, Cockburn and McHale (2006) who look at patent citations when workers move across firms, Irarrazabal, Moxnes and Ulltveit-Moe (2013) who argue that worker heterogeneity accounts for much of the exporting premium of firms, and De la Roca and Puga (2012) who look at mobility of workers across cities.

explain the productivity advantages through agglomeration (at both firm and local labor market levels)? While the issues analyzed in this paper are of general interest, the specific case of Veneto is also important. This region is part of a larger economic area in Italy where, as in Silicon Valley, networks of specialized firms, frequently organized in districts, have been effective in promoting and adapting to technological change during the past three decades. This so called ‘Third Italy’ region has received a good deal of attention by researchers, both in the United States and in Europe (Brusco, 1983; Piore and Sabel, 1984; Trigilia, 1990; Piore, 2009).

3 Framework and Empirical Strategy

3.1 Conceptual Framework

Consider a finite number of locations, each constituting a separate local labor market. To fix ideas, assume that these labor markets are completely segmented, with workers being immobile among them. There exists a finite collection $\mathcal{J} = \{\mathcal{J}_0, \mathcal{J}_1\}$ of firms consisting of the set \mathcal{J}_1 of *good* firms, which are more productive because they have some superior knowledge and set \mathcal{J}_0 of other (*non-good*) firms which have no access to superior knowledge. The superior knowledge is exogenously given and could include information about export markets, physical capital, process innovations, new managerial techniques, new organizational forms and intermediate inputs. Workers employed by good firms acquire some proportion of the firms’ internal knowledge.¹³ Workers are either *knowledgeable* or *unknowledgeable*. All workers employed by good firms, because of their access to the firm’s internal knowledge, are knowledgeable. Additionally, some proportion of this knowledge can be transferred to a $j \in \mathcal{J}_0$ firm if the workers switch employers.

¹³For simplicity, I assume that this acquisition of internal knowledge takes place immediately after the workers join the good firm. I also assume that this type of knowledge cannot all be patented and that exclusive labor contracts are not available.

The production function of firm $j \in \mathcal{J}_0$ is

$$Y_j = F(L_j, K_j, M_j) = A_j [L_j^\alpha K_j^\gamma M_j^\lambda]^\delta \quad (1)$$

where $L_j = H_j + N_j$, i.e. the sum of knowledgeable workers H_j (who moved at some point from a good firm to a non-good firm) and unknowledgeable workers, N_j ; K_j is total capital inputs, M_j is material inputs. The managerial technology involves an element of diminishing returns to scale, or to "span of control" ($\delta < 1$).¹⁴ I allow for knowledge transfer by letting productivity depend on H_j ¹⁵:

$$A_j = D_j e^{\beta_H H_j} \quad (2)$$

3.2 Empirical Strategy

I obtain the regression equation that forms the basis of my empirical analysis, by combining equation (1) and (2), and taking logs:

$$\ln(Y_{jst}) = \beta_L \ln(L_{jst}) + \beta_K \ln(K_{jst}) + \beta_M \ln(M_{jst}) + \beta_H H_{jst} + \beta_0 + \zeta_{jst} \quad (3)$$

The dependent variable in much of my analysis is the real value of total firm production; s denotes industry, l denotes locality and t denotes year.¹⁶ The variable of interest, H , the number of knowledgeable workers, is constructed from head counts in the matched employer-employee data.¹⁷ I define a worker as being knowledgeable (having recent experience at a good firm) in year t , if he or she is observed working in a good firm for one or more of the years $t - 3$ to $t - 1$. If a worker is hired at time $t - g$, and has experience at a good firm

¹⁴See Lucas (1978). This is in line with the large presence, that I document below, of small and medium size firms in the sample of non-good firms.

¹⁵See Section A.I for a discussion of the firm optimization problem.

¹⁶Subsection 5.3 reports estimation results for alternative specifications (in terms of functional forms and measures of productivity). Notice that $\beta_L = \delta\alpha, \beta_K = \delta\gamma, \beta_M = \delta\lambda$.

¹⁷In Section 5.4 I also employ an alternative, continuous, measure of the receiving firm's exposure to knowledge, which exploits the productivity differences between sending and receiving firms (in the spirit of Stoyanov and Zubanov (2012)), thus extending the baseline analysis which works with a dummy indicating experience at a good firm. Further, I present estimates when I lag the number of workers with experience at good firms.

between $t - g$ and $t - 3$, she contributes to H count from year $t - g$ until t .¹⁸ In what follows, I use the terms "knowledgeable workers" and "workers with recent experience at good firms" interchangeably.

The structure of regression equation (3) is in line with that in Greenstone, Hornbeck and Moretti (2010, GHM), who also regress firm-level output on inputs (and let productivity depend on the presence of large plants that generated bidding from local governments). The estimation of such productivity specification on balance sheet data allows me, in Section 6, to relate directly my findings regarding the effect of firm-to-firm labor mobility to the evidence in GHM.

In equation (3), the term $\ln(D_j)$ is decomposed into two elements, β_0 and ζ_{jst} . The constant β_0 denotes mean efficiency across all firms in \mathcal{J}_0 that is due to factors others than H . The time-variant ζ_{jst} represents deviations from this mean efficiency level and captures (a) unobserved factors affecting firm output, (b) measurement error in inputs and output, and (c) random noise. Estimating the effect of recruiting a knowledgeable worker on a firm's productivity is difficult in the presence of unobservable productivity shocks (contemporaneous or future). I turn now to describing what type of biases these *time-varying* unobservables may introduce and how I deal with them in the empirical work.

In Section 5.3 I discuss estimates using the within-transformation, to address the possibility that the estimated productivity gains are due to *time-invariant* unobservables such as managerial talent.

3.2.1 Unobserved Productivity shocks

Unobservable Contemporaneous Shocks I express the deviations from

¹⁸It may be instructive to consider a practical example. Consider a worker who separates from a good firm in 1994 and joins non-good firm j in 1995. Provided that the worker remains in j , she will be counted as a knowledgeable worker for every year from 1994 to 1997.

mean firm efficiency not resulting from knowledge transfer, ζ_{jst} , as

$$\zeta_{jst} = \omega_{jst}^* + \nu_{jst} = \mu_{st} + \varpi_{lt} + \omega_{jst} + \nu_{jst} \quad (4)$$

which specifies that ζ_{jst} contains measurement error ν_{jst} and a productivity component ω_{jst}^* (TFP) known to the firm but unobserved by the econometrician. The productivity component can be further divided into a firm-specific term (ω_{jst}), a term common to all firms in a given industry (μ_{st}) and a term common to all firms in a given locality (ϖ_{lt}). Equation (3) now becomes:

$$\ln(Y_{jst}) = \beta_0 + \beta_L \ln(L_{jst}) + \beta_K \ln(K_{jst}) + \beta_M \ln(M_{jst}) + \beta_H H_{jst} + \mu_{st} + \varpi_{lt} + \omega_{jst} + \nu_{jst} \quad (5)$$

One major difficulty in estimating β_H in Equation (5) is that non-good firms may decide on their choice of H based on the realized firm-specific productivity shock (ω_{jst}) unknown to the researcher¹⁹. In order to assess the relevance of this issue in my setting, I present in Section 5.1 estimates using control function methods drawn from the productivity literature (Olley and Pakes, 1996; Levinsohn and Petrin, 2003).

Unobservable Future Shocks: using the number of downsizing firms as IV It is also possible that knowledgeable workers are attracted to join firms that are on the rise, rather than knowledgeable workers moving to firms and causing the increase in productivity. Specifically, the number of knowledgeable workers may in principle also be correlated with productivity shocks happening in the future if workers can foresee them and apply for jobs at firms with better growth prospects. If such firms prefer to hire workers from good firms, these workers will have a higher probability of being chosen. To the extent that preferring workers from good firms can be explained through knowledge transfer from these firms, a positive correlation between H and the receiving firm's productivity shocks in $t + 1$ does suggest a role for labor mobility as a channel for knowledge transfer, even though it will overestimate its

¹⁹See Section A.I for a discussion using the first order condition with respect to H obtained from the optimization problem.

importance (Stoyanov and Zubanov, 2012). To address this reverse causality concern in Section 5.2 I present estimates where I instrument for the number of knowledgeable workers in a non-good firm with the number of *local* good firms in the *same 2-digit industry* that downsized in the previous period. Following a downsizing event at a good firm, it is more likely that a knowledgeable worker applies for a job at local non-good firms because she is unemployed and does not want to relocate far away. Put differently, in the scenario captured by the IV approach, the strategic mobility explanation is less likely to play a role.

One can think of two main reasons why good firms may downsize in a particular year: first, good firms may get a bad draw from the distribution of product-market conditions. Even though an inherent productivity advantage partly insulates the good firms from output shocks, sufficiently large shocks will pierce this insulation and induce the good firm to layoff workers. Secondly, good firms may downsize in a particular year due to offshoring.

The basic intuition behind the IV approach is to consider moves from workers whose former employer downsized due to demand shocks or offshoring. While the timing of these moves is arguably exogenous, these workers may still decide which new employer to join among the set of non-good firms. However, in small labor markets and specialized industries, workers may have a limited set of alternatives.

The choice of the instrument is based on the notion that geographic proximity plays an important role in determining worker mobility. In January 2012, I visited several Veneto firms and interviewed employees about the history of their enterprises and their current operations. I also conducted phone interviews with officials of employers' associations and chambers of commerce. My anecdotal evidence supports the idea that distance acts as a barrier for job mobility.²⁰ Moreover, in Section 4.2, I show descriptive evidence regarding the propensity of workers to change jobs within the same local labor market.

²⁰In a phone interview, Federico Callegari of the Treviso Chamber of Commerce, reasoned out the role of geographic proximity: "I think distance matters a lot for workers' job mobility. When losing their job, workers tend to look for another job with a commuting time of maximum 20-30 minutes. Why? Because they want to go home during the lunch break!"

In the presence of product demand shocks or offshoring, using the number of downsizing firms as an instrument is invalid if it cannot be excluded from the causal model of interest (Equation 3). The identifying assumption of my IV strategy is therefore that the number of downsizing good firms is correlated with the causal variable of interest, H , but uncorrelated with any other unobserved determinants of productivity. In Section 5.2, I discuss possible violations of the exclusion restrictions and describe my attempts at addressing them.

It is important to note that the number of downsizing local good firms is a convincing external instrument used in a production function framework. As pointed out in the survey by Eberhardt and Helmers (2010), to date only past values of the regressors themselves or input prices have been used for instrumentation in the production function literature.

Alternative approach: proxy for future shocks To explore the possibility of future productivity shocks further I adapt the Olley and Pakes (1996) and Levinsohn and Petrin (2003) approaches and also include in both t and $t + 1$ (a) polynomial functions of capital and investment, and (b) polynomial functions of capital and materials, in an effort to proxy for shocks that may be anticipated by the workers. This is in the spirit of Stoyanov and Zubanov (2012) and assumes that hiring firms are also able to anticipate their productivity shocks and adjust their inputs accordingly. In Section 5.1, I provide the estimates and a longer discussion of such approach. In Section 5.3 I also provide estimates when including polynomial functions of capital, materials and the number of employees in both t and $t + 1$. This specification is in the spirit of the Akerberg, Caves and Frazer (2006) approach.

3.2.2 Estimation of the Wage Model and Identification of Good Firms

Empirically, I identify potentially high-productivity firms as high-wage firms (HWFs): firms that pay a relatively high firm-specific wage premium. The use of alternative groupings of firms based on output controlling for inputs

and value added yields very similar results (See Section 5.3). The definition of high-productivity firms as HWFs (employed in my baseline analysis) is consistent with many recent models of frictional labor markets (e.g., Christensen et al., 2005), in which higher-productivity firms pay higher wages for equivalent workers. As I shall show below using balance sheet data, HWFs have significantly higher total factor productivity (TFP) and value added than other firms in my sample. There are three reasons why, for the baseline results, I use Social Security data to define good firms as HWFs (rather than define the good firms directly as the high TFP or high value added ones and detect them using balance sheet data). First, Social Security data are available for a longer period of time than the balance sheets, and, therefore, their use allows a more accurate categorization of firms. Second, since Social Security records are administrative data, measurement error is lower than in balance sheets. Third, Social Security data allow estimation of a worker-level wage equation, controlling for measured individual characteristics and worker effects. The estimated worker effects will also be helpful later in order to characterize knowledgeable workers and investigate the issue of unobserved labor quality when evaluating the productivity effect of labor mobility (Section 5.3).

Following Abowd, Kramarz and Margolis (1999, henceforth AKM), I specify a loglinear statistical model of wages as follows:

$$w_{ijt} = \theta_i + \psi_j + X'_{it}\beta + \varepsilon_{ijt} \quad (6)$$

where the dependent variable, the log of the average daily wage earned by worker i in firm j in year t , is expressed as a function of individual heterogeneity, firm heterogeneity, and measured time-varying characteristics.²¹ The presence of labor mobility in matched worker-firm data sets (like the one I use) enables the identification of worker and firm effects.

A concern for estimation arises from the possibility of mobility based on the value of worker-firm match. In equation (6) ψ_j represents the wage premium

²¹The vector X'_{it} includes tenure, tenure squared, age, age squared, a dummy variable for manager and white collar status, and interaction terms between gender and other individual characteristics.

paid to all employees in firm j , regardless of the features of the particular employees. Nevertheless, if the AKM exogenous mobility assumption is violated due to sorting based on the value of a worker-firm match component, and workers switch jobs to join firms to which they are better matched, then the wage premium would include a match component that would be specific to each employee-firm j pair, and no longer common across all employees in firm j . To test for such sorting, I perform three analyses: first, I look at wage changes for job switchers, second, I compare the fit of the AKM model with the one of a model including match (worker-firm) fixed effects²², and third I examine the residuals from AKM. I present both analyses below. To summarize, I find little support for mobility based on the value of worker-firm match, consistent with Card, Heining and Kline (2013) and Macis and Schivardi (2013) results on German and Italian data respectively.²³ More details can be found in Section A.III.

For the baseline analysis, I identify good firms as those whose estimated firm fixed effects fall within the top third of all estimated firm effects. Section 4.1 reports descriptive results as well as more details on the estimation procedure. In what follows, I use the terms "high-wage firms" (HWFs) and "good firms" interchangeably.

Results are very similar if I identify good firms as those whose estimated firm fixed effects fall within the top third of the estimated firm effects *within industry*. In Section 5.4, I remove the top third threshold and employ a continuous, measure of the receiving firm's exposure to knowledge. This alternative

²²This is a fully saturated model which contain a separate dummy for each job.

²³More specifically, the absence of a mobility premium for the movers who remain in the same firm-effect quartile (Figure A.1) suggests that idiosyncratic worker-firm match effects are not the main driver of job mobility. Also, the symmetry between wage increases for job changers from low to high quartiles and the wage decreases for job changers in the opposite direction (Figure A.2), and the absence of notable systematic patterns in the distribution of residuals for particular types of matches (Figure A.3) are in line with the AKM model. Finally, the improvement in fit of a match fixed effects regression compared to the AKM model is very small. Notice that small match effects in wages do not automatically indicate small match effects in productivity however, as employees may have low bargaining power vis-à-vis their employers. In Section 5.3 I explore the possibility of match effects in productivity.

measure is the difference in quality between the sending and the receiving firm defined for each new worker i hired from more productive firms than the receiving firm j , multiplied by the number of such workers in j . The larger the value, the higher the exposure of the receiving firm to the knowledge coming from the sending firms. This procedure extends the baseline analysis which works with a dummy indicating experience at a good firm.

4 Data and Descriptive Statistics

The data used in this paper covers the region of Veneto, an administrative region in the Northeast of Italy with a population of around 5 million people (8 percent of the country's total). During the period of analysis (1992-2001), the labor market in Veneto has been characterized by nearly full employment, a positive rate of job creation in manufacturing and positive migration flows (Tattara and Valentini, 2010). The dynamic regional economy features a large presence of flexible firms, frequently organized in districts with a level of industrial value-added greatly exceeding the national average. Within the district, larger lead firms often play an important role by coordinating a ring of capable input providers in the context of evolving international markets.²⁴ Manufacturing firms in Veneto specialize in metal-engineering, goldsmithing, plastics, furniture, garments, textiles, leather and shoes.²⁵ The manufacture of food and beverage, and wine and baked goods, in particular, is also a prominent subsector.

My data set pools three sources of information: individual earnings records, firm balance sheets, and information on local labor markets (LLMs).²⁶ The earnings records come from the Veneto Workers History (VWH) dataset. The VWH has data on all private sector personnel in the Veneto region. Specif-

²⁴See Whitford (2001) for a discussion. The most famous industrial concentration is the eyewear district in the province of Belluno, where Luxottica, the world's largest manufacturer of eyeglasses, has production plants.

²⁵Benetton, Sisley, Geox, Diesel, and Replay are Veneto brands.

²⁶The first two sources, combined for the period 1995-2001, have been used in the study on rent-sharing, hold-up and wages by Card, Devicienti and Maida (2014).

ically, it contains register-based information for virtually any job lasting at least one day. A complete employment history has been reconstructed for each worker.

Balance sheets starting from 1995 were obtained from AIDA (Analisi Informatizzata delle Aziende), a database circulated by Bureau Van Dijk containing official records of all incorporated nonfinancial Italian firms with annual revenues of at least 500,000 Euros. AIDA's balance sheets include firms' location, revenues, total wage bill, the book value of capital (broken into subgroups), value added, number of employees, value of materials and industry code. I use firm identifiers to match job-year observations for workers aged 16-64 in the VWH with firm financial data in AIDA for the period 1995-2001. Further details on the match and data restrictions I make, as well as descriptive information are provided in Section A.II.

Information on LLMs is obtained from the National Institute of Statistics (ISTAT). The LLMs are territorial groupings of municipalities characterized by a certain degree of working-day commuting by the resident population. In 1991 the 518 municipalities or *comuni* in Veneto are divided into 51 LLMs.

4.1 AKM Estimation and Descriptive Results

This Section reports descriptive results for the firms in my sample, as well as more details on the AKM estimation procedure. The method in Abowd, Creedy and Kramarz (2002) identifies separate groups of workers and firms that are connected via labor mobility in matched employer-employee data. When a group of workers and firms is connected, the group contains all persons who ever worked for any firm within the group and all firms at which any of the persons were ever employed. I run the grouping algorithm separately using VWH data from 1992 to 2000 for firms that could be matched in AIDA.²⁷ I then use the created group variable to choose the largest group as a sample for my fixed-effects estimation - Equation (6). Details on sample restrictions and descriptive information are provided in Appendix A.II.

²⁷I experimented with other choices for the period of the AKM estimation, such as 1991-2000 or 1992-1999. Results are very similar.

I identify HWFs as those firms whose firm effects rank in the top third of the sample. Column 1 of Table 1 shows that HWFs pay on average 13 percent higher wages than non-HWFs²⁸. For labor mobility to generate productivity benefits, a firm-specific advantage should be observed at good firms that could be the basis for knowledge transfer to other local firms. I therefore estimate equations such as:

$$\ln O_{jst} = \beta_0 + \beta_1 HWF_j + \mu_{st} + \varpi_{lt} + controls_{jt} + e_{jst} \quad (8)$$

where the dummy HWF takes the value of 1 if firm j is classified as high-wage during the period 1992-2000 (the years over which the AKM estimates are obtained) and O_{jst} represents different firm-level outcomes over the period 1995-2001 (the years over which balance sheet data are available). The different firm-level outcomes are total factor productivity (output as dependent variable controlling for capital, material and labor inputs), value added, capital intensity (fixed assets as dependent variable controlling for firm size) and intangible capital intensity (intangible fixed assets - intellectual property, accumulated research and development investments and goodwill - as dependent variable controlling for firm size). Column 2-5 of Table 1 shows the results.

[TABLE 1 AROUND HERE]

In the Veneto manufacturing sector clear differences between HWFs and non-HWFs emerge: HWFs feature on average 8 percent higher total factor productivity, 11 percent higher value added, 10 percent higher capital intensity and 27 percent higher intangible capital intensity. This evidence is important for establishing the potential for knowledge transfer in the region.

²⁸This finding emerges from the estimation of

$$w_{ijt} = X'_{it}\beta + \theta_i + \beta_1 HWF_j + \varepsilon_{ijt} \quad (7)$$

where the dummy HWF takes the value of 1 if firm j is classified as high-wage.

4.2 The Extent of Labor Mobility

For labor mobility to be a mechanism for transfer of knowledge, we must observe some workers moving from HWFs to other firms. This section documents the extent of labor mobility between HWFs and non-HWFs from 1992 to 2001. For this period, I observe around 52,000 incidents of job change. These moves are categorized according to the direction of the flows in Table A.3. Column 1 shows that around 7,700 of these moves are from HWFs to non-HWFs. Column 2 and 3 distinguish between moves within and moves across LLMs. They show that moves within the same LLM happen more frequently.²⁹ Column 4 and 5 distinguish between moves within and moves between two-digit industries. Around 35% of the moves from HWFs to non-HWFs are within the same industry. The remaining moves are to a non-HWF in one of the nineteen 2-digit industries other than the one in which the worker has HWF experience.

Table A.4 shows the share of knowledgeable workers in non-HWFs (Column 1) and the share of non-HWFs employing knowledgeable workers, i.e. firms with $H > 0$ (Column 2). The proportion of knowledgeable workers in non-HWFs is defined as the number of knowledgeable workers observed at non-HWFs divided by the total number of workers in the Veneto region employed by non-HWFs (i.e. employees at non-HWFs with $H = 0$ or $H > 0$). In 1995, only 0.5% of the total employees in non-HWFs had recent HWF experience. In 2001 this share doubled to 1%. In terms of the potential for knowledge transfer, the relevant question is how knowledgeable workers spread across the sample of non-HWFs. The share of firms employing knowledgeable workers is much greater than the share of such workers: around 18% in 1995 and around 29% in 2001. Therefore, during my sample period, an increasing percentage of firms employed knowledgeable workers.

4.2.1 Characteristics of Knowledgeable Workers

Overall I observe 6539 unique knowledgeable workers. As regards to individual characteristics of the movers in my sample, Table A.5 shows that knowledge-

²⁹In Section A.IV I further discuss the relation between geography and labor mobility.

able workers observed at non-HWF tend to be more likely to be male, white collars and managers than non-HWFs workers without recent experience at good firms. They also tend to be older.³⁰ For a comparison of the distribution of the estimated θ_i , see Section 5.3.

5 Evidence on Worker Flows and Productivity

In this section I evaluate the extent to which non-HWFs benefit from hiring workers from HWFs during the period 1995-2001. Details on sample restrictions and descriptive statistics for the variables used in the regression analysis are provided in Appendix A.II.

5.1 Estimates using OLS and control function methods

Table 2 shows the estimation results using OLS and control function methods. I cluster standard errors at the firm level. Coefficients associated with the H variable in Table 2 represent semielasticities because my variable of interest is not in logarithms. This choice for the baseline specification, which directly follows from Equation (2), is founded on the fact that H takes on the value 0 for a large number of observations (Figure 1). Thus, any possible transformation of the H measure could possibly affect the associated estimated parameters.³¹

[TABLE 2 AROUND HERE]

Column 1 reports estimate from the baseline OLS specification: the coefficient on H_{jst} is positive (0.03) and significant. In Columns 2 and 3, I use control function methods drawn from the productivity literature in order to address potential endogeneity arising from unobservable productivity shocks.³² Although the point estimates of the coefficients for H_{jst} in the Olley and Pakes

³⁰In terms of months of HWF experience, the minimum is 11 months, and the mean is 32 months.

³¹Results using different functional forms are discussed in Section 5.3.

³²Recall the discussion in Section 3.2.1. See Section A.V for a discussion of the Olley and Pakes (1996) and Levinsohn and Petrin (2003) approaches, and the estimation details.

(1996, henceforth OP) and Levinsohn and Petrin (2003, henceforth LP) specifications are smaller than the baseline estimate, none of the specifications is qualitatively inconsistent with the empirical finding that non-HWFs benefit from hiring workers from HWFs.

The extent to which non HWFs benefit from hiring workers from HWFs may be overestimated in Column 1-3 in the presence of productivity shocks happening in the future if workers can foresee them and apply for jobs in firms with better growth prospects (as discussed in Section 3.2.1). In Section 5.2, I show results from the IV strategy. Columns 4 and 5 of Table 2 show the estimates from an alternative approach to address the issue of future productivity shocks: I add polynomial functions of capital and investments or capital and materials in t and $t + 1$. These estimates also suggest that non-HWFs benefit from knowledgeable workers by experiencing increased productivity.³³

Overall, the main empirical result discussed so far is that non-HWFs benefit from hiring workers from HWFs. The point estimates suggest that the average effect of recruiting a knowledgeable worker on a non-HWF's productivity is an increase of between 1.8 and 3 percent. This seems like a large effect. However, recall also that non-HWFs are quite small: the median number of employees at non-HWFs is 33. Further, as many as 78 percent of non-HWFs in a given year do not employ any knowledgeable workers. Hiring one knowledgeable worker therefore implies a significant change for most firms in my data. It may also be instructive to evaluate the average magnitude of TFP change in monetary terms. Multiplying the estimated percentage change by the mean value of non-HWF output, this calculation indicates that the increase in TFP due to hiring a worker from HWFs is associated with an increase in total output of 154-256 thousands of 2000 euros. ³⁴

³³That said, many components in the polynomial approximations are statistically significant, implying that these extra terms contribute in explaining the variation in productivity among firms. Notice the drop in observations due to the fact that I am using the leads of inputs (polynomials in $t + 1$).

³⁴Stoyanov and Zubanov (2012) find that the productivity gains associated with hiring from more productive firms are equivalent to 0.35 percent per year for an average firm. Parrotta and Pozzoli (2012) find the impact of the recruitment of knowledge carriers on a firm's value added is an increase of 1%-2%. Balsvik (2011) finds that workers with MNE experience contribute 20% more to the productivity of their plant than workers without

5.2 IV Estimates

In this section, I instrument for the number of knowledgeable workers in a non-good firm by using the number of good firms in the same LLM and same 2-digit industry that downsized in the previous period. This IV strategy aims at addressing the concern of strategic mobility whereby workers may be attracted to join firms that are on the rise. Turning to the details of the instrument, a firm is defined as a "downsizing firm" if its employment decreased by more than 1 percent *compared to the previous year's level*. The division of good firms into downsizing and non-downsizing firms according to this criterion is less sensible for small firms. Thus, I impose the additional condition that the decrease in employment is greater than or equal to three individuals.³⁵ The exclusion restriction is violated and $\widehat{\beta}_H^{IV}$ is biased upward if there are localized unobservable industry shocks that would both lead good firms to downsize and *positively* affect productivity at non-HWFs. I discuss in detail my investigation of possible violations of the exclusion restriction below.

Table 3 shows the results from the IV estimation of Equation (3). Standard errors are clustered at the level of the LLM.

[TABLE 3 HERE]

The estimated coefficient of H , the number of knowledgeable workers, in Column 1 is quite large (0.143). Recall the OLS estimates: the coefficient on knowledgeable workers is 0.03. A tentative explanation for the magnitude of the IV results is that the effect of knowledgeable workers may be heterogeneous across firms. If there are indeed heterogeneous effects of H on productivity, then consistent OLS measures the average effect of H on productivity across all firms. Two Stage Least Squares (TSLS) on the other hand estimates the average effect for the firms that are marginal in the recruitment decision, in the sense that they recruit knowledgeable workers if and only if there exists

such experience.

³⁵The instrumental variable is summarized in Table A.7, together with other variables constructed at LLM level that are used in the analysis.

excess local supply.³⁶ If the effect of knowledgeable workers on productivity is larger for non HWFs that are marginal in the recruitment decision, the TSLS estimates will exceed those of consistent OLS.³⁷ In practice, however, the IV standard errors are quite large (0.067) and prevent me from drawing definitive conclusions.

It is also important to emphasize that downsizing of a good firm is not a likely event. In Section 6 I evaluate the extent to which labor mobility can explain the productivity advantages of firms located near other highly productive firms. Those calculations take into account the probability of downsize, and therefore deliver a similar conclusion when using either the OLS or the IV estimate of β_H to study the extent to which worker flows explain the productivity gains experienced by incumbent firms when new highly productive firms are added to a LLM.

A concern for the validity of the exclusion restriction arises from the observation that the dependent variable in my econometric model is the *value* of output.³⁸ Unobserved shifts in local demand from the products of HWFs to the products of non-HWFs might simultaneously lead to a downsizing by HWFs, higher output prices for non-HWFs, and the hiring of HWF employees by non-HWFs. The LLM-year effects control for local demand shocks, but localized unobservable *industry* shocks may still play a role. Consequently, it is possible that $\widehat{\beta}_H^{IV} > 0$ reflects higher output prices, rather than higher productivity due to labor mobility. I do not expect this to be a major factor in my study: manufacturing firms in my sample generally produce goods traded outside the LLM.³⁹ To explore this possibility further, I add a dummy

³⁶See Imbens and Angrist (1994) for a discussion. For a recent example, see Eisensee and Strömberg (2007).

³⁷In principle, the IV estimates are also consistent with the idea that, since the good firms pay a relatively high firm-specific wage premium, workers who separate from a good firm may be of lower quality. I refer to this potential adverse selection problem as "lemons bias" (Gibbons and Katz, 1991). Lemons bias will tend to work against the finding of a positive effect of knowledgeable workers: in such scenario the OLS coefficient will be biased downward because of this negative selection.

³⁸The theoretically correct dependent variable in a productivity study is the *quantity* of output, but, due to data limitations, this study (and virtually all the empirical literature on productivity) uses price multiplied by quantity.

³⁹Imagine the extreme case of a non-HWF that produces a nationally traded good in a

in Column 2 taking the value of one if the industry produces goods that are not widely traded outside the LLM.⁴⁰

Even when the level of tradability is controlled for, the effects of product demand might still be relevant and may bias $\widehat{\beta}_H^{IV}$ if an industry is strongly localized. In such a scenario, the negative shock to the local HWF may lead to increased demand for the non-HWF firm j even though the HWF and the non-HWF produce a tradable good.⁴¹ To address this concern, I construct an index of industry localization as follows: $r_s = (\text{Italian Firms in } s)/(\text{Veneto Firms in } s)$. Industries with low r have a relatively small number of firms outside the Veneto area. In Column 3, I enter r_s as additional regressor. The results in Column 2 and 3 are very similar to those in Column 1.

Finally, in column 4, I use an alternative definition of downsizing firms: a downsizing firm must see an employment reduction larger than 3 percent *compared to the previous year's level*.⁴² The results are largely unchanged. Overall, the estimates show that the productivity effect of labor mobility is at least in part independent of unobserved future productivity shocks that are correlated with the propensity to hire workers with experience at highly productive firms.

5.3 Validity and Robustness

The main empirical result so far in the first part of the paper is that non-HWFs benefit from hiring workers from HWFs. I now investigate the robustness of the estimates to various specifications and explore several possible alternative explanations for the estimated effects. Specifically, I evaluate the role of unob-

perfectly competitive industry. Its output prices would not increase disproportionately if the LLM experienced an increased demand for its good.

⁴⁰See Section A.VI for details.

⁴¹Suppose that an industry is strongly localized and most of the firms producing that particular good in Italy are in the same Veneto LLM. Then the non-HWF may experience an increase in demand, and hence in price, after the negative shock to a local HWF that is a direct competitor in the national market.

⁴²I keep the additional condition that the decrease in the labor force is greater than or equal to three individuals.

served worker quality, present additional specifications addressing endogeneity concerns (time invariant firm level heterogeneity and time-varying unobservables), discuss estimates using alternative groupings of firms, and perform further robustness checks (value-added specification and the investigation of the role of functional form assumptions).

Unobserved Worker Quality As mentioned above, a potential threat to identification is the fact that I do not observe worker quality. To investigate this issue, Figure 2 shows a plot of the quantiles of the distribution of $\hat{\theta}_i$'s, the worker fixed effects obtained from estimating equation (6), for unobservable workers (workers at HWFs with no experience at good firms) against the quantiles of the distribution of $\hat{\theta}_i$'s for the switchers from good firms. Points on the right-hand side of the 45-degree line mean that the values of the distribution on the x-axis are higher than those of the distribution on the y-axis.⁴³ Since many points are on the left-hand side of the main diagonal, it seems reasonable to conclude that workers coming to non-HWFs from HWFs are (in large part) not positively selected on unobserved ability.

In Table A.8 I also show evidence, from regression analysis exploiting moves from non-HWFs, that it is inconsistent with an explanation to my findings of a productivity effect of labor mobility based on unobservable worker quality.

Additional specifications addressing endogeneity concerns I start by addressing the issue of unobservables related with new hires. If workers who recently changed firms are more productive than stayers, the effect of newly hired workers with HWF experience may equally apply to newly hired employees without HWF experience. Also, the estimated productivity gains may be driven by better worker-firm matching rather than knowledge transfer. In order to explore these possibilities, I first define medium-wage-firms (MWFs) as those whose estimated firm fixed effects from the AKM model fall between the 33th percentile and the 67th percentile of all estimated firm effects, and

⁴³Both axes are in units of the estimated θ_i from equation 6 (vertical axis for unobservable workers and horizontal axis for the hires from good firms). For a given point on the q-q plot, the quantile level is the same for both points.

low-wage-firms (LWFs) as those whose estimated firm fixed effects fall below the bottom third. I then construct a new variable, denoted by N : the number of new hires that do not have HWF experience. I then estimate for the sample of MWFs:

$$\begin{aligned} \ln(Y_{mst}) = & \beta_0 + \beta_L \ln(L_{mst}) + \beta_K \ln(K_{mst}) + \beta_M \ln(M_{mst}) + \\ & + \beta_H H_{mst} + \beta_N N_{mst} + \mu_{st} + \varpi_{lt} + v_{mst} \end{aligned}$$

In this specification, the identification of knowledge transfer relies on the differential effect of hiring an employee with recent HWF experience over hiring an employee from a LWF. By including both H and N , any potential bias caused by the correlation between unobservables and new hires is removed. Column 1 of Table A.8 shows the results. The coefficient of H is positive and significant. The coefficient of N is positive but much smaller. The difference in productivity premiums associated with the two types of newly hired workers is significant at the 1% level. The introduction of N , in the spirit of Balsvik (2011), can also be seen as a placebo test at firm-level and it suggests that the productivity effect attributed to knowledgeable workers is not associated with recently hired workers in general: large productivity gains from hiring seem to be realized only when new hires come from more productive firms. While I cannot completely rule out the possibility that at least some of the estimated effect reflects better worker-firm matching, or switchers being more productive than stayers in general (i.e. regardless of the previous employment history), this evidence lends credibility to the knowledge transfer hypothesis. It is also inconsistent with an explanation to my findings based on unobservable worker quality. If the estimates of a positive and significant β_H were driven by higher ability of workers moving from HWFs to MWFs, then β_N would be negative and significant, since hiring labor from non-HWFs would cause a decline in firm m 's average worker quality and therefore diminish its productivity (Stoyanov and Zubanov, 2012).

Next, in Column 2 of Table A.8 I show estimates using the within-transformation in order to explore the possibility that the estimated productivity gains are

due to time-invariant unobservables. This would be the case for instance if the (long-run) stable hiring patterns are due to certain management practices (Stoyanov and Zubanov, 2012). The estimates in Column 2 should be interpreted cautiously because the within estimator is known from practical experience to perform poorly in the context of production functions (Eberhardt and Helmer, 2010).⁴⁴ The problem of using the within-transformation is the removal of considerable information from the data, since only variation over time is left to identify the parameters. If this concern is set aside, the results show a positive and significant coefficient on H .

Furthermore, considering the differences in observable characteristics documented in Appendix 4.2 between movers from HWFs and other workers at non HWFs, in Column 3 I augment Equation (3) with the share of females, managers, blue-collar and white-collar workers, and differently aged workers at each firm. The estimate of β_H in Column 3 is in line with the results from Table 2.

In Column 4, I include polynomial functions of capital, materials and the number of employees in both t and $t+1$. This specification is in the spirit of the Akerberg, Caves and Frazer (2006) approach. The estimates in Column 4 of Table A.8, together with the IV results, and the estimates in Column 4 and 5 of Table 2 indicates that the productivity effect of labor mobility is at least in part independent of unobserved future productivity shocks that are correlated with the propensity to hire workers with experience at highly productive firms.

Alternative groupings of firms As an additional sensitivity check, I classify potential good firms as firms with high TFP. Specifically, I estimate firm effects from a total factor productivity specification (i.e. one in which the dependent variable is output, and I control for inputs). I identify good firms as those whose estimated firm fixed effects fall within the top third of all estimated firm effects. The results, shown in Table A.9 are very similar to those

⁴⁴Indeed, estimates in Column 2 indicate severely decreasing returns to scale, likely due to measurement error in the input variables, whose influence is exacerbated by the variable transformation.

in Table 2. I also experimented with a grouping of firm based on the estimated firm fixed effects in a value added specification. Results were largely unchanged.

Additional robustness checks Table A.10 shows results from further robustness checks. In Column 1, I show that results are robust when using value-added as an alternative measure of economic performance. Columns 2-5 investigate the role of functional form assumptions. Until now, I have presented results based on specifications where the intensity of potential knowledge transferred is measured by the number of H workers. In Column 2, I model this intensity as the share of workers with recent experience at good firms, dividing H by L .⁴⁵ In Column 3, I estimate:

$$\ln(Y_{jst}) = \beta_0 + \beta_L \ln(L_{jst}) + \beta_K \ln(K_{jst}) + \beta_M \ln(M_{jst}) + \beta_{H_i} \log(H_{jst}) + \delta 1(H_{jst} = 0)_{jst} + \mu_{st} + \varpi_{lt} + v_{jst}$$

Compared to Equation (3), I replaced H_{jst} with its logarithm, and I imposed $\log(H_{jst}) = 0$ for the observations with $H_{jst} = 0$. Plus, I added the dummy $1(H = 0)_{jst}$ taking value 1 if the number of knowledgeable workers is equal to 0.

Column 4 allows the effect of each input to vary at the two-digit industry level. This specification accounts for the possibility that different industries use different technology or employ inputs of different quality. In Column 5, inputs are modeled with the translog functional form. My findings are robust to the different functional form assumptions in Columns 2 to 5.

⁴⁵Since there may be measurement error in L , the number of employees in the AIDA data, a potential problem with such specification arises. Rewrite equation (3) as $\ln(\frac{Y_{jst}}{\theta L_{jst}}) = \beta_K \ln(K_{jst}) + \beta_M \ln(M_{jst}) + \beta_h h_{jst} + \mu_{st} + \varpi_{lt} + v_{jst}$. Since $h = H/L$, a mechanical relationship between h and the dependent variable may arise at time t . To address this issue, I use L obtained from head counts in the Social Security dataset.

5.4 Further Extensions

Results for Labor Mobility within and between Industry Sectors

An interesting question is whether the knowledge embedded in workers is general enough to be applied in different industries: Column 1 of Table A.11 distinguishes between workers with HWF experience moving within the same two-digit industry and workers moving between industries. The coefficient of both type of knowledgeable workers moving is significant and positive. This is consistent with knowledge transfer by labor mobility being able to overcome technology borders between industries.

Results by Worker Occupation I now investigate whether new hires occupation influences the strength of the effect on the receiving firm productivity. I consider heterogeneity in knowledgeable workers' occupation both within their sending (HWF) and receiving (non-HWF). Specifically, knowledgeable workers are grouped into higher-skilled and lower-skilled occupations. The higher-skilled occupation category includes white collars and managers. The lower-skilled occupation includes blue collars and apprentices.

In Column 2 of Table A.11, the main variable of interest is disaggregated into two groups based on the occupation at the previous employer (HWF). In Column 3 it is disaggregated based on the occupation at the current employer (non-HWF). By and large, the estimates are consistent with the hypothesis that workers in higher-skilled occupation are better able to transfer knowledge. In both columns, coefficients on both variables are positive and significant, but the point estimate on the productivity effect is larger for switchers in higher-skilled occupations, with the differential impact being significant at conventional levels.

Continuous measure of the receiving firm's exposure to new knowledge

In Column 4 of Table A.11, I employ a continuous measure of the receiving firm's exposure to knowledge, drawn from Stoyanov and Zubanov (2012), which exploits the differences between sending and receiving firms. This procedure extends the analysis above which has so far worked with a

dummy indicating experience at a HWF. The new measure of firm’s exposure to knowledge is calculated for each firm j hiring at time t as follows:

$$exposure_{j,t} = \left[\sum_{i=1}^{G_{j,t}} D_{i,t} (\widehat{\psi}_i^s - \widehat{\psi}_j^r) \right] \cdot G_{j,t}$$

where $\widehat{\psi}_i^s$ and $\widehat{\psi}_j^r$ are the estimated AKM firm effects of the sending and receiving firms, $G_{j,t}$ is the number of new workers and $D_{i,t}$ is an indicator variable equal to one if $(\widehat{\psi}_i^s - \widehat{\psi}_j^r) > 0$ and zero otherwise. In words, the new measure is the difference in quality between the sending and the receiving firm defined for each new worker i hired from more productive firms than the receiving firm j , multiplied by the number of such workers in j . The larger the value, the higher the exposure of the receiving firm to the knowledge coming from the sending firms. The estimates confirm that non HWFs benefit from hiring workers from HWFs.⁴⁶

Lagged number of knowledgeable workers In Column 5 of Table A.11, I lag the number of workers with HWF experience. The coefficient is again positive and significant.

6 Worker flows and agglomeration advantages

In this Section, I evaluate the extent to which labor mobility can explain the productivity advantages of firms located near other highly productive firms. Greenstone, Hornbeck and Moretti (2010, GHM) find that, following the opening of a large manufacturing plant, the total factor productivity (TFP) of incumbent plants in the US counties that were able to attract these large plants increased significantly relative to the TFP of incumbent plants in counties that survived a long selection process but narrowly lost the competition. I am able to evaluate the extent to which worker flows explain the productivity advan-

⁴⁶A non-HWF hiring at the mean *exposure* is shown to feature 0.13 percent higher productivity compared to an observationally identical firm that hired no one.

tages of agglomeration by predicting the change in local productivity following an event analogous to that studied by GHM within the worker mobility framework described above. More specifically, I study the effect of an increase in the number of good firms such that the change in local output is comparable to the output of the average large plant whose opening is considered by GHM.⁴⁷

I focus on a change in the number of good local firms *belonging to the same industry as firm j* . This is motivated by Henderson (2003), Cingano and Schivardi (2004), Moretti (2004) and GHM who found that local spillovers are increasing in economic proximity. An overview of my procedure is as follows. Denote the number of knowledgeable workers *moving within industry* observed at firm j with H^{ind} . First, I estimate the effect on H^{ind} of a change in the number of good local firms belonging to the same industry as firm j . Recall that if a worker is hired at time $t - g$, and has experience at a HWF between $t - g$ and $t - 3$, she contributes to H count from year $t - g$ until t . This implies that H^{ind} exhibits a certain degree of persistence and suggests estimation of a dynamic model for the number of workers observed at firm j who have HWF experience in the same industry. Second, I predict the change in H^{ind} that each of the non HWFs in a LLM would experience if an output increase similar to the one considered by GHM were to occur, and I multiply the predicted change in H^{ind} by $\widehat{\beta}_H^{ind}$, the estimated coefficient on H^{ind} in my productivity regression. This product yields the predicted change in productivity due to worker flows for a given Veneto firm if its local industry were to experience an increase in output analogous to that considered by GHM.

Finally, I compare my estimate of the predicted contribution of worker flows to productivity changes with GHM’s estimate of the overall productivity

⁴⁷The large plants in GHM generated bidding from local governments, almost certainly because there was a belief of important positive effects on the local economy. GHM observe that the mean increase in TFP after the opening is larger if incumbent plants are economically close to the large plant - measures of economic links are a dummy indicating belonging to the same industry, and indicators of technological linkages and workers flows at industry level. Further, the TFP effect increases over time. These facts are consistent with the presence of intellectual externalities that are embodied in workers who move from firm to firm. I think of the plants considered by GHM as “good” plants, and in order to simulate their experiment, I consider a change in the number of Veneto good firms such that the change in local output is comparable.

effect. This comparison allows me to have a sense of the extent to which worker flows can explain the productivity gains experienced by other firms when high-productivity firms in the same industry are added to a LLM.

I will now discuss the issues related to the implementation of the first step, i.e. the estimation of the dynamic effect on H_j^{ind} of a change in the number of good firms in the same locality and industry.

6.1 A dynamic model for the number of knowledgeable workers

Consider a model of the form

$$H_{jlst}^{ind} = aH_{jst,t-1}^{ind} + bGood_Firms_{ls(j)t} + e_{jlst} \quad (9)$$

$$e_{jlst} = m_j + v_{jlst}$$

$$E[m_j] = E[v_{jlst}] = E[m_j v_{jlst}] = 0 \quad (10)$$

where $Good_Firms_{ls(j)t}$ is the number of local good firms in the same industry of firm j . Recall that the superscript *ind* represent workers moving within industry. The disturbance term e_{jlst} has two orthogonal components: the firm effect, m_j and the idiosyncratic shock, v_{jlst} . Using OLS to estimate Equation (9) is problematic because the correlation between $H_{jst,t-1}^{ind}$ and the firm effect in the error term gives rise to "dynamic panel bias" (Nickell, 1981). Application of the Within Groups estimator would draw the firm effects out of the error term, but dynamic panel bias would remain (Bond, 2002). Therefore I employ the first-difference transform, proposed by Arellano and Bond (1991):

$$\Delta H_{jlst}^{ind} = a\Delta H_{jst,t-1}^{ind} + b\Delta Good_Firms_{ls(j)t} + \Delta v_{jlst} \quad (11)$$

The firm effects have now disappeared, but the lagged dependent variable is still potentially endogenous as the $H_{jst,t-1}^{ind}$ in $\Delta H_{jst,t-1}^{ind} = H_{jst,t-1}^{ind} - H_{jst,t-2}^{ind}$ is correlated with the $v_{jst,t-1}$ in $\Delta v_{jlst} = v_{jst,t} - v_{jst,t-1}$. However, appropriately lagged values of the levels of the regressors remain orthogonal to the error

and are available for use as instruments. Blundell and Bond (1998) show that under appropriate assumptions about the initial conditions, we can use appropriately lagged values of the differences of the regressors as instruments for the equation in levels. In the GMM system estimator, which I employ below, the orthogonality conditions for the differenced equation (11) are augmented by the orthogonality conditions for the level equation (9).

In principle, another challenge in estimating (11) is that firms in a given industry do not select their location randomly. Firms maximize profits and decide to locate where their expectation of the present discounted value of future profits is greatest. This net present value differs across locations depending on many factors, including transportation infrastructure, subsidies, etc. These factors, whose value may be different for firms in different industries, are unobserved, and they may be correlated with ΔH_{jlst}^{ind} . It should be noted, however, that a positive shock in the LLM j and industry s such that there is entry of HWFs (i.e. $\Delta Good_Firms_{ls(j)t} > 0$) makes it *less* likely that a non-HWFs is going to hire from a good firm in the same industry. This is because the shock is *good news* for good firms, so in principle it should make it less likely for the labor force at the good firms to experience a decrease, and in turn, it should make it less likely for a non-HWF to hire from a good firm. The bias introduced by the fact that good firms do not choose their location randomly is therefore likely to be downwards, and thus working against the finding of a positive effect of $\Delta Good_firms_{ls(j)t}$ on ΔH^{ind} . In any case, $\Delta Good_Firms_{ls(j)t}$ is treated as endogenous in the estimation.

Table 4 gives the results of estimating Equation (11) for the period 1992-2001. I include time dummies in order to remove universal time-related shocks from the errors.⁴⁸

[TABLE 4 AROUND HERE]

Column 1 uses the system GMM estimator. I restrict the instrument set to lags 3 and longer, as suggested by the result of the Arellano-Bond test for

⁴⁸Since these specifications do not require information collected from AIDA balance sheets, the sample period is not restricted to post-1995 observations.

serial correlation.⁴⁹ The regression shows a positive and significant coefficient of the number of good local firms (\widehat{b}), in line with the descriptive evidence discussed above of an important role of geographic and economic proximity in determining worker mobility. Column of Table 4 also shows a positive and significant coefficient for the lagged dependent variable (\widehat{a}). The economic significance of \widehat{a} and \widehat{b} is described below (see discussion of Table 5 in Section 6.2). The p-value of the Hansen test for overidentifying restrictions does not suggest misspecification.

In Column 2, I estimate the model with two-step system GMM and Windmeijer (2005)-corrected cluster-robust errors.⁵⁰ In Column 1-2, for all variables only the shortest allowable lagged is used as instrument. In Column 3-4, I estimate the same specification in Column 1 including lags up to 4 and 5, respectively. The estimates in Columns 2 to 4 are similar to those in Column 1.

6.2 Effect of Labor Mobility on LLM Productivity.

Having estimated the dynamic effect on H_j^{ind} of a change in $Good_Firms_{ls(j)t}$, I can predict the change in H , and hence in productivity, that a non-HWF in Veneto would experience after an output increase similar to the one considered by GHM. As it turns out, the large manufacturing plants whose openings are studied by GHM are much larger than the typical good firm in Veneto.⁵¹ In order to observe a change in local output comparable to the typical output increase caused by the opening of one large plant in GHM, a Veneto locality must experience an increase of 56 HWFs. This is the shock I consider for my calculations of the effect of labor mobility on LLM productivity.

⁴⁹Arellano and Bond (1991) develop a test for autocorrelation in the idiosyncratic disturbance term v_{jlst} . It checks for serial correlation of order l in levels by looking for correlation of order $l + 1$ in differences. I employ this test below.

⁵⁰See Roodman (2009) for a detailed discussion of two-step GMM and Windmeijer-correction.

⁵¹This is due both to the fact that new entrants in GHM are significantly larger than the average new plant in the United States and the fact that the Veneto region is characterized by the presence of small and medium-sized businesses, whose size is smaller than the typical firm in United States. See Section A.VII for descriptive statistics.

The predicted change in H that a typical non-HWF would experience after 5 years, the time horizon considered in GHM, is then $\widehat{\Delta H}^{ind,5\ years} = 56 \cdot (b + ab + a^2b + a^3b + a^4b + a^5b)$. This change in H can be obtained using the estimates for a and b in Equation (11) from Table 4. In order to obtain the predicted change in productivity, I use $\widehat{\beta}_H^{ind}$ from the estimation of Equation (3). The results using the different approaches (baseline OLS, OP, LP, polynomial functions of capital and investments or capital and materials in t and $t + 1$, and IV) are shown in Table A.12. The predicted change in productivity attributable to worker flows five years after the local output increase is then equal to $\widehat{\Delta TFP}^{ind,5\ years} = \widehat{\Delta H}^{ind,5\ years} \cdot \widehat{\beta}_H^{ind}$. In the case of the IV, the number of new entrants is multiplied by the probability of downsizing. Table 5 provides a summation of the calculations concerning the effect of labor mobility on LLM productivity. The predicted change in productivity attributable to worker flows five years following a large local output increase ranges from 1.3 to 2.2 percent depending on the specification. The final step is to compare the magnitude of $\widehat{\Delta TFP}^{ind,5\ years}$ with GHM's estimate of the overall productivity effect caused by a local output increase. The increase in productivity estimated by GHM five years after the opening for incumbent plants in the same two-digit industry is 17 percent. Hence, my calculations indicate that worker flows explain 8-13 percent of the agglomeration advantages estimated by GHM, with the mean of the point estimates being 10 percent.⁵² Overall, these results suggest that worker flows explain an economically relevant proportion of the productivity gains experienced by other firms when HWFs in the same industry are added to a LLM.

6.3 Further LLM-level analysis

Labor-market based knowledge spillovers and worker-firm matching

Recall my previous discussion of the agglomeration literature. A consensus has

⁵²The remaining portion of the overall local productivity change observed after the event is likely to be explained by other types of knowledge spillovers not related to labor mobility (i.e. various forms of communication externalities) and the availability of specialized intermediate inputs.

emerged that agglomeration economies can at least partially explain why firms cluster next to each other. Disagreement remains, however, over the sources of these agglomeration effects. In the above, I emphasized the possibility that knowledge is embedded in workers and diffuses when workers move between firms. The strong localized aspect of knowledge spillovers discussed in the agglomeration literature may thus arise from the propensity of workers to change jobs within the same local labor market.

Another explanation that has been proposed within the literature for the agglomeration of economic activity is the possibility of advantages from thick labor markets. The argument is that agglomeration allows a better match between employer needs and worker skills, which may result in higher productivity (Helsley and Strange, 1990). In order to explore the relevance of this mechanism in the Veneto manufacturing sector context, in Section A.VIII, I estimate a production function for non-HWF firm j in industry s and LLM l augmented by both the number of good firms and the number of non-good firms in industry s and LLM l . I show that the local productivity effect attributed to good firms does not appear to be associated with a general increase in the size of the labor market: large productivity gains linked to changes in the number of firms seem to be realized only when the new entrants are good firms. This evidence suggests that the estimated impact does not reflect better worker-firm matching arising from a thicker labor market.

7 Conclusions

Localized knowledge spillovers are a common explanation for the productivity advantages of agglomeration.⁵³ Nevertheless, as pointed out by Combes and Duranton (2006), if information can easily flow out of firms, the question of why the effects of spillovers are localized must be clarified.

This paper directly examined the role of labor mobility as a mechanism

⁵³The availability of specialized intermediate inputs, the sharing of a labor pool, and better matching have also garnered attention in the literature's attempt to explain agglomeration economies.

for the transfer of efficiency-enhancing knowledge, and evaluated the extent to which labor mobility can explain the productivity advantages of firms located near other highly productive firms. The underlying idea is that knowledge is embedded in workers and diffuses when workers move between firms. The strong localized aspect of knowledge spillovers discussed in the agglomeration literature may thus in part arise from the propensity of workers to change jobs within the same local labor market.

In order to empirically assess the importance of labor-market based knowledge spillovers, I used Social Security earnings records and detailed financial information for firms from the Veneto region of Italy. The main empirical task involved showing that the observed associations between labor mobility and productivity were at least partly causal. I implemented several strategies to support a causal explanation, which include control function methods, IV strategy, and placebo tests. While none of these strategies is completely conclusive in regard to identification, together they gave evidence consistent with a causal interpretation of the observed labor mobility effects and inconsistent with the plausible alternative explanations.

The empirical evidence presented using this unique dataset points to the concrete possibility that agglomeration of economic activity creates important productivity advantages at the local level. The productivity benefits to a non-HWF from being located in a cluster with a large number of good firms rest with the opportunities to hire workers whose knowledge was gained in good firms. Such knowledge can be successfully adapted internally. More specifically, the regression analysis showed that hiring a worker with HWF experience increases the productivity of other (non-HWF) firms. My findings imply that worker flows explain a significant portion of the productivity gains experienced by incumbent firms when HWFs in the same industry are added to a local labor market.

Figure 1: *Distribution of H (number of knowledgeable workers) across firms*

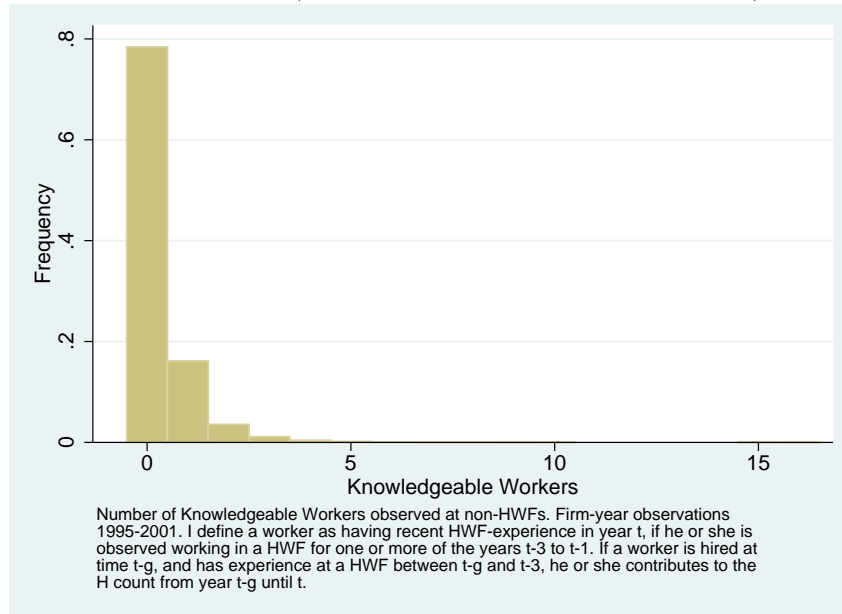

Figure 2: *Q-Q Plot: Worker Effects*

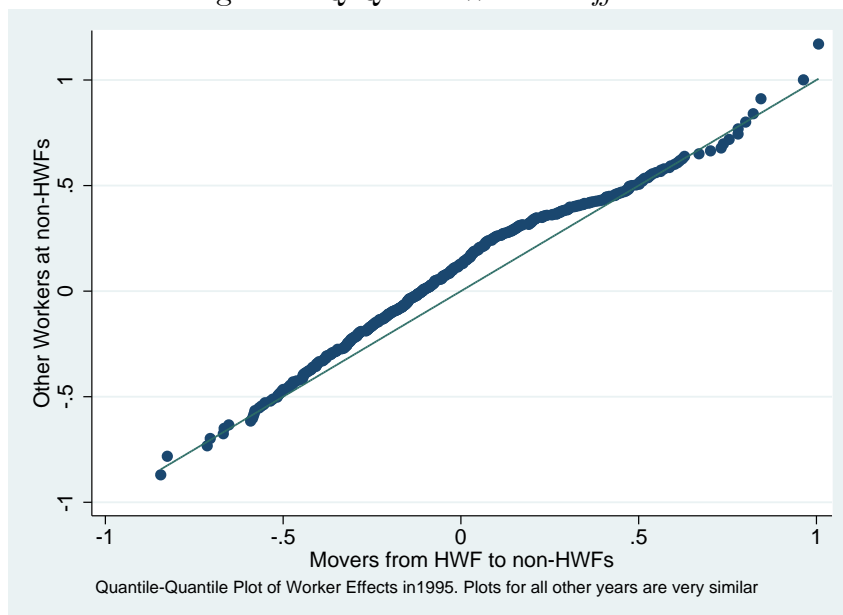

Table 1: Characteristics of HWFs

	(1)	(2)	(3)	(4)	(5)
	Individual	TFP	Value	K	Intangible
	Wage		Added		K
HWF	0.130 (0.003)	0.080 (0.008)	0.105 (0.010)	0.101 (0.025)	0.274 (0.043)
Observations	1837597	26657	26587	26674	24450
Adj. R-squared	0.912	0.920	0.800	0.496	0.210

The Table shows that in the Veneto manufacturing sector clear differences between HWFs and non HWFs emerge. This evidence is important for establishing the potential for knowledge transfer in the region. The dummy HWF takes value 1 if the firm is classified as high-wage during the period 1992-2000 (the years over which the AKM estimates are obtained). Dependent Variables are in logs. In Column 1 the dependent variable is individual wage. In Column 2-5 the different firm-level outcomes are total factor productivity (output as dependent variable controlling for capital, material and labor inputs), value added, capital intensity (fixed assets as dependent variable controlling for firm size) and intangible capital intensity (intangible fixed assets - intellectual property, accumulated research and development investments and goodwill - as dependent variable, controlling for firm size). Output, Value Added and Capital variables are in 1000's of 2000 euros and are measured over the period 1995-2001 (the years over which balance sheet data are available). Standard errors (in parentheses) clustered by firm.

Table 2: Knowledgeable Workers and Productivity in non-HWFs, 1995-2001

	(1)	(2)	(3)	(4)	(5)
	OLS	OP	LP	Inv-Cap Interactions t,t+1	Mat-Cap Interactions t,t+1
log(capital)	0.092 (0.005)	0.087 (0.019)	0.148 (0.010)		
log(materials)	0.583 (0.007)	0.587 (0.007)		0.617 (0.012)	
log(employees)	0.223 (0.006)	0.225 (0.010)	0.202 (0.006)	0.187 (0.014)	0.177 (0.006)
H workers	0.030 (0.003)	0.018 (0.004)	0.021 (0.003)	0.018 (0.006)	0.022 (0.003)
Observations	17158	6635	17158	2963	13540
Adj. R-squared	0.931			0.940	0.952

Dependent variable: Log(Output). Standard errors (in parentheses) clustered by firm. H workers is the number of workers with HWF experience currently observed at non-HWFs. Column 1 reports estimates from the baseline specification. Column 2 implements the procedure in Olley and Pakes (1996). Column 3 implements the procedure in Levinsohn and Petrin (2003). Column 4 adds a third-degree polynomial function of log capital and log investment and the interaction of both functions in t and $t+1$. Column 5 includes the same controls as col. 4 but replaces log investment with log materials.

Table 3: Knowledgeable Workers and Productivity in non-HWFs, IV Estimates 1995-2001

	(1) Baseline	(2) tradability	(3) localization	(4) Larger drop in L
H workers	0.143 (0.067)	0.143 (0.067)	0.147 (0.066)	0.172 (0.083)
log(capital)	0.085 (0.008)	0.085 (0.008)	0.084 (0.008)	0.083 (0.008)
log(materials)	0.575 (0.013)	0.575 (0.013)	0.575 (0.013)	0.573 (0.014)
log(employees)	0.204 (0.010)	0.204 (0.010)	0.203 (0.010)	0.199 (0.011)

Adj. R-squared	0.914	0.914	0.914	0.909
Fstat, instrum., 1st stage	13.82	13.81	14.14	10.39

Dependent variable: $\text{Log}(\text{Output})$. Standard errors (in parentheses) clustered by LLM (47). Regressions include industry-year interaction dummies and LLM-year interaction dummies. Column 1 reports IV estimates using the lagged number of downsizing local good firms in the same 5-digit industry. A good firm is considered as downsizing if the drop in L is larger than 1 percent. The decrease in the labor force must also be greater than or equal to three individuals. Column 2 adds an indicator of the importance of local demand, namely a dummy taking value 1 if the 4-digit industry produces goods that are not widely traded outside the LLM. Column 3 controls for an index of industry localization, namely the ratio between the number of firms in Veneto and total Italian firms in a given 4-digit industry. In Column 4 a good firm is considered as downsizing if the drop in L is larger than 3 percent. The controls are the same as in Column 3.

Table 4: Number of local HWFs in same Industry and Knowledgeable Workers moving within industry, System GMM Estimates, 1992-2001

	(1)	(2)	(3)	(4)
	Baseline	Twostep	Lags up to 4	Lags up to 5
lag(H from same Ind)	0.144 (0.0719)	0.136 (0.0653)	0.147 (0.0717)	0.159 (0.0660)
Local HWFs in same Ind	0.009 (0.0012)	0.009 (0.0012)	0.010 (0.0015)	0.009 (0.0014)
Observations	25688	25688	25688	25688
AR(1)z	-2.124	-2.436	-2.172	-2.337
AR(2)z	-6.062	-6.339	-6.057	-6.010
AR(3)z	0.304	0.196	0.337	0.460
HansPv	0.321	0.321	0.607	0.941

Dependent variable: 'H from same Ind', the number of H workers that moved into a non-HWF from an HWF belonging to the same industry. Standard errors (in parentheses) clustered by LLM. Regressions include year dummies. The variable 'Local HWFs in same industry' is treated as endogenous. Column 1 reports the baseline System GMM results. Column 2 estimates the model with two-step System GMM with Windmeijer-corrected standard errors. I restrict the instrument set to lags 3 and longer. In Column 1-2 for all variables only the shortest allowable lagged is used as instrument. In Column 3 and 4 lags up to 4 and 5 are used, respectively. AR(1)z, AR(2)z and AR(3)z: Arelanno and Bond (1999) test of first, second and third order serial correlation, distributed as N(0,1). HansPv: p-value of Hansen test of overidentifying restrictions.

Table 5: Worker flows and agglomeration advantages

	(1)	(2)	(3)	(4)	(5)	(6)
	OLS	OP	LP	Inv-Cap Interactions t,t+1	Inv-Mat Interactions t,t+1	IV
$\widehat{\beta}_H^{ind}$	0.036	0.037	0.031	0.022	0.026	0.121
Probability of HWF downsize	0.178
$\widehat{\Delta TFP}^{ind, 5 years} = \widehat{\Delta H}^{ind, 5 years} * \widehat{\beta}_H^{ind}$	0.021	0.022	0.018	0.013	0.015	0.013
$\widehat{\Delta TFP}^{ind, 5 years} / \text{overall agglom. effect}$	0.125	0.128	0.107	0.076	0.090	0.075

This table provides a summation of the predicted change in productivity that is attributable to worker flows five years following a local output increase. The predicted changes are calculated for each of the different functional forms (i.e. $\widehat{\beta}_H^{ind}$ is obtained using OLS, OP, LP, polynomial functions of both capital and investments and capital and materials, and IV). Simulating results to correspond to the large plant opening results found in GHM such that one large plant opening is equivalent to 56 small Veneto plants, this table provides evidence that worker flows explain an important portion of the agglomeration advantages found in GHM.

Web Appendix (not for publication)

A.I The firm problem, and the role of productivity shocks

Consider a firm j 's optimization problem in each time period:

$$\max_{L_j, K_j, M_j} \pi_j = A_j [L_j^\alpha K_j^\gamma M_j^\lambda]^\delta - w_0 N_j - w_1 H_j - \rho K_j - \tau M_j - f(H_j) \quad (12)$$

where w_0 and w_1 are the wages paid by firm j for unknowledgeable and knowledgeable workers, respectively (both are industry-wide equilibrium wages); the term $f(H_j)$ captures the cost of recruiting knowledgeable workers (due to search frictions for instance). I assume $f' > 0$, $f'' > 0$, $f'(0) = 0$.⁵⁴ For readability I drop the time subscript (since all terms are contemporaneous), and industry and locality subscripts. The corresponding first-order condition for H_j is⁵⁵

$$\frac{\partial \pi}{\partial H_j} = \beta_{H_j} D e^{\beta_{H_j} H_j} [(N_j + H_j)^\alpha Q_j]^\delta + \delta D e^{\beta_{H_j} H_j} [(N_j + H_j)^\alpha Q_j]^{\delta-1} \times (\alpha(N_j + H_j)^{\alpha-1} Q_j) - w_1 - f'(H_j) = 0 \quad (13)$$

where $Q_j = K_j^\gamma M_j^\lambda$. Solving (13) for D , we have that

$$D = \frac{w_1 + f'(H_j^*)}{(K_j^\gamma M_j^\lambda)^\delta e^{\beta_{H_j} H_j} \left[\beta_{H_j} (H_j^* + N_j)^\alpha + \delta \alpha (H_j^* + N_j)^{\alpha-1} \right]}$$

Taking first-order conditions with respect to N and M and combining them with the above expression yields⁵⁶ :

$$D = \frac{w_1 + f'(H)}{\left(\frac{w_0}{\tau}\right)^{\alpha-1} K^\gamma \delta e^{\beta_H H} \left(w_0 \left(\frac{\tau}{w_0}\right)^{\lambda\delta} \frac{1}{AK^\gamma \delta}\right)^{\frac{\alpha}{\lambda\delta + \delta\alpha - 1}} \left[\beta_H \left(w_0 \left(\frac{\tau}{w_0}\right)^{\lambda\delta} \frac{1}{AK^\gamma \delta}\right)^{\frac{1}{\gamma\delta + \delta\alpha - 1}} \frac{w_0}{\tau} + \delta\alpha \right]} \quad (14)$$

If $f(\cdot)$ is convex enough, then this equation gives us the optimal H_j^* , with $\frac{dH_j^*}{dD} > 0$, i.e., there is a positive relationship between D and H_j .⁵⁷ In such case, when employing OLS to estimate Equation (5) without accounting for the existence

⁵⁴This in order to avoid corner solutions (i.e. the firm hiring only knowledgeable workers).

⁵⁵Recall that $L_j = H_j + N_j$ and $A_j = D_j e^{\beta_H H_j}$

⁵⁶I consider K as a state variable, in line with the recent productivity literature.

⁵⁷Essentially, because H_j affects productivity, one needs to ensure that the marginal recruiting cost $f'(\cdot)$ increases sufficiently fast so that the firm has decreasing returns to scale.

of the firm-specific productivity shock ω_{jst} , the bias induced by endogeneity between H_j and ω_{jst} is positive (positive productivity shocks translate into higher probability to hire from HWFs), implying that the coefficient estimate will be biased upward ($\widehat{\beta}_{H_j} > \beta_{H_j}$).⁵⁸

A.II Sample Restrictions, AKM Estimation Details and Additional Descriptive Information

Following Card, Devicienti, Maida (2014), I use firm identifiers to match job-year observations for workers aged 16-64 in the VWH with firm financial data in AIDA for the period 1995-2001. The match rate is fairly high: at least one observation in the VHW was found for over 95 percent of the employers in the AIDA sample, and around 50 percent of employees observed in the VWH between 1995 and 2001 can be matched to an AIDA firm. Most of the nonmatches seem to be workers of small firms that are omitted from AIDA. In sum, I was able to match at least one employee for around 18,000 firms, or around 10 percent of the entire universe of employers contained in the VWH.⁵⁹ From this set of potential matches I execute two exclusions to obtain my estimation sample for Equation (6). First, I remove all workers outside manufacturing. Next, I exclude job-year observations with remarkably high or low values for wages (I trim observations outside the 1 percent - 99 percent range).

The method in Abowd, Creedy and Kramarz (2002) identifies separate groups of workers and firms that are connected via labor mobility in the data. I run the grouping algorithm separately using VHW data from 1992 to 2000 for firms that could be matched in AIDA. I then use the created group variable to choose the largest group as the sample for my fixed-effects estimation. Figure A.4 shows the distribution of estimated firm effects.⁶⁰ I identify HWFs as

⁵⁸Recall that $\ln(D_j) = \beta_0 + \zeta_{jst}$ and $\zeta_{jst} = \omega_{jst} + \mu_{st} + \varpi_{lt} + \nu_{jst}$ where the firm-specific productivity shock (ω_{jst}) is unknown to the researcher.

⁵⁹Average firm size for the matched jobs sample (36.0 workers) is considerably larger than that for total employers in the VWH (7.0 workers). Mean daily wages for the matched observations are also greater, while the fractions of under 30 and female employees are lower.

⁶⁰In order to implement the approach in Abowd, Creedy and Kramarz (2002), I use the

those firms whose firm effects rank in the top third of the sample.⁶¹ Table A.1 summarizes the sample of HWFs. Figure A.5 shows the geographical variation in the number of HWFs across LLMs. Table A.2 compares HWFs and non HWFs in terms of workforce characteristics.⁶² Table A.6 summarizes the sample of non HWFs used in the main firm-level analysis – equation (3).⁶³ The main analysis is performed over the period for which balance sheet data are available (1995-2001).

A.III Mobility based on the value of worker-firm match

To test for mobility based on the value of worker-firm match (see discussion in Section 3.2.2), I follow Card, Heining and Kline (2013) and Macis and Schivardi (2013) and perform three analyses: first, I look at wage changes for job switchers, second, I compare the AKM regression with a regression including match fixed effects, and third I examine the residuals from AKM. I present these analyses below.

A.III.1 Wage changes for job switchers

I consider all job switchers in the years 1992-2001 with at least two consecutive years at the old and new employer. I then categorize the source and destination

a2reg Stata routine developed by Ouazad (2007).

⁶¹Results are very similar if I identify good firms as those whose estimated firm fixed effects fall within the top third of the estimated firm effects *within industry*.

⁶²Notice that since the specifications in Table A.2 do not require information collected from AIDA balance sheets, the sample period is not restricted to post-1995 observations.

⁶³In order to obtain this firm-level estimation sample I first remove the HWFs. From this non-HWF sample I remove (a) firms that close during the calendar year and (b) firm-year observations with remarkably high or low values (outside the 1% - 99% range) for several key firm-level variables, such as total value of production, number of employees, capital stock and value of materials, share of workers with recent experience at good firms (obtained dividing H by L) (c) firms in LLM with centroids outside Veneto (3 LLMs). I then attempt to reduce the influence of false matches, particularly for larger firms, by implementing a strategy of Card, Devicienti and Maida (2014) to eliminate the "gross outliers", a minor number of matches (less than 1% of all employers) for which the absolute gap between the number of workers reported in a firm's AIDA balance sheet and the number found in the VWH is larger than 100.

jobs based on the quartiles of the estimated ψ_j 's. I form sixteen cells based on quartiles of source and destination, and calculate average wages of switchers in each cell in the two years before the switch and the two years after the switch. Under the exogenous mobility assumption, workers who move between employers that pay comparable wages should not experience any wage change. Further, workers who move from a “high ψ ” to a “low ψ ” employer should experience a wage loss and workers who move in the reverse way a wage gain. Moreover, the wage decrease for the former set and the wage increase for the latter set be approximately symmetrical – the “ ψ ” lost by one set should be approximately the same of that lost by the other set. Figure A.2 and A.3 show patterns consistent with such implications of the exogenous mobility assumption. The absence of a mobility premium for the movers who remain in the same firm-effect quartile suggests that idiosyncratic worker-firm match effects are not the main driver of job mobility. Also, the symmetry between wage increases for job changers from low to high quartiles and the wage decreases for job changers in the opposite direction are in line with the AKM model

A.III.2 Contrast of AKM and match fixed effects regression

If match effects are significant, a model with worker-firm fixed effects (i.e. a fully saturated model which contain a separate dummy for each job) should out-perform the AKM model as regards to statistical fit. I find that for the AKM: Adj R-squared = 0.91, Root MSE = 0.077; for the match fixed effects regression Adj R-sq = 0.92, Root MSE = 0.084. Even if these results show the presence of a match component in wages, the improvement in fit of a match fixed effects regression compared to the AKM model is very small

A.III.3 Analysis of the residuals from AKM

I also analyze the residuals from the AKM regression. Specifically, I form deciles based on the estimated worker effects and firm effects, and calculate average residuals in each of the 100 worker x firm decile cell, to examine whether there are any notable systematic patterns in the distribution of resid-

uals for particular types of matches. The absence of such patterns (Figure A.3) supports the conclusion that in the Veneto manufacturing sector context, the additively separable firm and worker effects obtained from the AKM model represent sound measures of the unobservable worker and firm components of wages.

A.IV Geography and Labor Mobility: Further Discussion

There exist at least two reasons why geographic proximity might be important for observed worker flows. First, distance may act as a barrier for workers' job mobility because of commuting costs or idiosyncratic preferences for location. Descriptive statistics in Combes and Duranton (2006) show that labor flows in France are mostly local: about 75% of skilled workers remain in the same employment area when they switch firms. The degree of geographical mobility implied by this figure is small, since the average French employment area is comparable to a circle of radius 23 kilometers. In Dal Bo', Finan and Rossi (2013), randomized job offers produce causal estimates of the effect of commuting distance on job acceptance rates. Distance appears to be a very strong (and negative) determinant of job acceptance: applicants are 33% less likely to accept a job offer if the municipality to which they are assigned is more than 80 kilometers away from their home municipality. The estimates in Manning and Petrongolo (2013) also suggest a relatively fast decay of job utility with distance. Another reason geographical proximity may be an important determinant of job mobility is that the firm's informational cost of identifying the "right" employee are larger across localities than within them. A similar argument can be made for the informational costs for workers.

A.V Discussion of Olley and Pakes (OP) and Levinsohn and Petrin (LP) approaches, and estimation details

OP construct an explicit model for the firm’s optimization problem in order to obtain their production function estimator. Essentially, the authors address the issue of endogeneity of inputs by inverting the investment function to back out—and thus control for—productivity. Building on OP, LP suggest the use of intermediate input demand in place of investment demand as a proxy for unobserved productivity. See Eberhardt and Helmers (2010) for an in-depth discussion of these ‘structural’ estimators. I use the *opreg* Stata routine developed by Yasar, Raciborski and Poi (2008) and I use the *levpet* Stata routine developed by Petrin, Poi and Levinsohn (2004), respectively. H_{jst} is treated as a freely variable input. I do not observe investment, and hence for Column 2 of Table 2 I derived a proxy variable in t as the difference between the reported book value of capital at time $t + 1$ and its value in t . The way I constructed the proxy variable somehow exacerbates the measurement error problems typically associated with the proxy variable approach. In addition, augmenting my specification with this proxy variable reduces my sample size substantially, as (a) many firm-year observations are lost when I take the difference in reported book values and (b) the OP approach requires positive values for the proxy variable, eliminating additional firm-year observations. (The estimation routine will truncate firms’ non-positive proxy variable observations because the monotonicity condition necessary to invert the investment function, and hence back out productivity, does not hold for these observations.)

A.VI Non-Tradable Goods

In Subsection 5.2 I used a dummy taking value one if the industry produces goods that are not widely traded outside the LLM. Industries for which the dummy takes value one are those classified as local industries by Weiss (1974): Bottled and Canned Soft Drinks and Carbonated, Mineral, and Plain Waters; Fluid Milk; Bread and Other Bakery Products, Except Cookies and Crackers;

Manufactured Ice; Primary Forest Products; Newspapers; Commercial Printing (except Lithographic); Commercial Printing (Lithographic); Engraving and Plate Printing; Typesetting; Photo-Engraving; Electrotyping and Stereotyping; Ready-Mix Concrete.

A.VII Local Labor Market Effect of Labor Mobility: Calculations Details

Table 1 in GHM reports statistics for the sample of plants whose opening is considered in their study. These plants are quite large: they are more than twice the size of the average incumbent plant and account for roughly nine percent of the average county's total output one year prior to their opening. The mean output (five years after their assigned opening date) is 452,801, 000 of year-2006 dollars, or 395,476,000 of year-2000 euros. Standard deviation is 901,690, 000 of year-2006 dollars. As explained in the notes of Table 1 in GHM, these statistics are for a subset of the 47 plant openings studied by the authors. In particular, a few very large outlier plants were dropped so that the mean would be more representative of the entire distribution (those dropped had output greater than half of their county's previous output and sometimes much more).

In order to establish the increase in the number of HWFs that a Veneto locality must experience to observe a change in local output comparable to the output increase caused by the opening of one large plant in GHM, I need to obtain the value of output for a typical HWF. Instead of dropping very large outlier plans as in GHM, I take the median of the distribution. The median value of output for HWFs in my sample is 7110 thousand of year-2000 euros. Therefore a Veneto locality must experience an increase of $395,476,000/7,110,000=56$ HWFs. This is the shock I consider for my calculations of the effect of labor mobility on LLM productivity.

A.VIII Labor-market based knowledge spillovers and worker-firm matching: Estimation Details

In order to explore the possibility of advantages from thick labor markets, I estimate a production function for non-HWF firm j in industry s and LLM l augmented by both the number of good firms and the number of non-good firms in industry s and LLM l .

$$\begin{aligned} \ln(Y_{jst}) = & \tilde{\beta}_0 + \tilde{\beta}_L \ln(L_{jst}) + \tilde{\beta}_K \ln(K_{jst}) + \tilde{\beta}_M \ln(M_{jst}) + b_G \text{Good_Firms}_{js(j)t} (+) \\ & + b_N \text{Non - Good_Firms}_{js(j)t} + \varrho_{jst} \end{aligned} \quad (15)$$

I use both OLS and the System GMM estimator proposed by Blundell and Bond (1998). When using the latter, both the number of good firms and

the number of non-good firms are treated as endogenous (I experiment with different lags of the instruments). The results are shown in Table A.13. The number of good firms is positively and statistically significantly related to an increase in the productivity of non-HWF j . The coefficient of the number of non-good firms is either negative and significant or insignificant depending on the specification. The difference in productivity effects associated with each type of firm is significant. This introduction of *Non - Good_Firms* can also be seen as a placebo test at LLM-level and it suggests that the local productivity effect attributed to good firms is not associated with an increase in the size of the labor market in general: large productivity gains linked to changes in the number of firms seem to be realized only when the firms are good. Although I am not able to entirely discard the chance that at least part of the estimated impact reflects better worker-firm matching arising from a thicker labor market, this finding supports the hypothesis of labor-market based knowledge spillovers in the Veneto manufacturing sector context.

employees age > 45	13.201	(31.794)	0	795	13643
Downsize	0.178	(0.383)	0	1	12485
Larger Downsize	0.164	(0.37)	0	1	12485

Sample includes 1887 Individual Firms in the period 1995-2001. Output, Capital, Materials, Value Added are in thousands of 2000 euros. Employees from AIDA refers to the values found in the AIDA balance sheet data. Employees from VWH refers to the values obtained from head count in the Veneto Worker History data from Social Security. The variable Downsize takes value 1 if the drop in the labor force is larger than 1 percent, and the decrease in the labor force is greater than or equal to three individuals. The variable Larger Downsize takes value 1 if the drop in the labor force is larger than 5 percent, and the decrease in the labor force is greater than or equal to three individuals.

Table A.2: Characteristics of HWFs Workforce, 1992-2001

	(1)	(2)	(3)	(4)	(5)
	share	share	share	share	share
	white coll.	manager	female	age < 30	age > 45
HWF	0.022	0.004	-0.034	-0.003	-0.003
	(0.004)	(0.001)	(0.005)	(0.005)	(0.004)
Observations	42845	42845	42845	42845	42845
Adj. R-squared	0.214	0.112	0.556	0.156	0.126

All OLS regressions include year and 4-digit industry dummies. Standard errors (in parentheses) clustered by firm. The dummy HWF takes value 1 if the firm is classified as high-wage after estimating the AKM model on the period 1992-2000.

Table A.3: Job changes by direction of mobility

	All	Within LLM	Across LLM	Within ind.	Across ind.
HWF to HWF	12,461	8,112	3,999	6,980	5,481
HWF to non-HWF	7,732	4,097	3,398	2,688	5,044
non-HWF to HWF	12,831	7,065	5,501	5,087	7,744
non-HWF to non-HWF	28,709	18,175	10,011	12,395	16,314
Total	61,733	37,449	22,909	27,150	34,583

Note: The total moves in the within LLM and across LLM columns do not sum to the column with all moves; this is because some firms are missing a LLM identifier. Moves to and from these firms could not be classified as within or across LLM.

Table A.4: Share of knowledgeable workers in non-HWFs and share of non-HWFs employing knowledgeable workers.

Year	Share of knowledgeable workers (percent)	share of non-HWFs with $H > 0$ (percent)
1995	0.54	17.8
1996	0.70	21.4
1997	0.66	18.6
1998	0.73	19.6
1999	0.72	22.3
2000	0.81	23.4
2001	1.02	29.0

This table displays the proportion of knowledgeable workers in non-HWFs and the proportion of all non-HWFs that employ knowledgeable workers. The proportion of knowledgeable workers in non-HWFs is defined as the number of knowledgeable workers observed at non-HWFs divided by the total number of workers in the Veneto region employed by non-HWFs (i.e. employees at non-HWFs with $H=0$ or $H > 0$).

Table A.5: Characteristics of knowledgeable vs. non-knowledgeable workers in non-HWFs.

Variable	Knowledgeable workers			Non-knowledgeable workers			T-test of diff. of means	
	Mean	(Std. Dev.)	N	Mean	(Std. Dev.)	N	Diff.	(Std. Err.)
age	34.227	(8.17)	678	35.659	(9.961)	142,536	-1.432***	(0.383)
female	0.215	(0.411)	678	0.326	(0.469)	142,536	-0.110***	(0.018)

Knowledgeable workers (i.e. workers with recent HWF experience) observed in non-HWFs in 1995.

Tables for all other years are very similar. Overall I observe 6539 unique knowledgeable workers.

Table A.6: non-HWFs, Main Estimation Sample

Variable	Mean	(Std. Dev.)	Min.	Max.	N
Output	8536.626	(9745.812)	1101.159	94712.109	17158

materials	4328.5	(5795.519)	85.084	52073.469	17158
value added	2163.3	(2418.32)	-4082.134	36787	17158
Tangible Capital	1737.3	(2336.372)	2.833	20677.465	17158
Intangible Capital	148.471	(437.372)	0	12792.205	17158
firm age (years)	17.843	(10.864)	0	117	17158
employees from AIDA	49.717	(49.68)	2	450	17158
employees from VWH	50.835	(47.996)	11	482	17158
blue collars	31.079	(31.419)	0	348	17158
white collars	10.076	(13.123)	0	253	17158
managers	0.682	(1.881)	0	54	17158
female employees	13.572	(19.61)	0	309	17158
employees age < 30	14.59	(14.48)	0	201	17158
employees age > 45	9.348	(13.285)	0	199	17158
H workers	0.305	(0.727)	0	16	17158
H from same Ind	0.093	(0.384)	0	13	17158
H from diff Ind	0.212	(0.586)	0	16	17158
Exposure	0.05	(0.168)	0	5.602	17158

Sample includes 3528 Individual Firms in the period 1995-2001. Output, Capital, Materials, Value Added are in thousands of 2000 euros. Employees from AIDA refers to the values found in the AIDA balance sheet data. Employees from VWH refers to the values obtained from head count in the sending and the receiving firm defined for each new worker i hired from more productive firms than the receiving firm j , multiplied by the number of such workers in j . The larger the value, the higher the exposure of the receiving firm to the knowledge coming from the sending firms.

Table A.7: Local Variables: Summary Statistics, 1995-2001

Variable	Mean	(Std. Dev.)	Min.	Max.	N
lag (downsiz. HWFs)	1.026	(1.553)	0	11	17158
lag (downsiz. HWFs, larger drop)	0.937	(1.433)	0	10	17158
Local HWFs in same Ind	2.078	(6.236)	0	54	17158
Local non-HWFs in same Ind	6.854	(10.382)	1	54	17158
Lag 5 (Local HWFs in same Ind)	2.547	(4.92)	0	39	17158
Lag 5 (Local non-HWFs in same Ind)	9.133	(11.724)	1	50	17158

Table A.8: Knowledgeable Workers and Productivity in non-HWFs: additional specifications addressing endogeneity concerns

	(1) Experience HWFs/LWFs	(2) Within	(3) Workforce Characteristics	(4) Mat-Cap-Lab Interactions t,t+1
log(capital)	0.097 (0.007)	0.065 (0.005)	0.091 (0.005)	
log(materials)	0.585 (0.011)	0.596 (0.013)	0.573 (0.007)	
log(employees)	0.224 (0.009)	0.060 (0.004)	0.229 (0.006)	
H workers	0.022 (0.004)	0.010 (0.002)	0.029 (0.003)	0.012 (0.003)
Recent LWF exp	0.003 (0.002)			
$\beta_{\tilde{H}}^{HWF} = \beta_{\tilde{N}}^{LWF}, pv$	0.000			
Observations	8791	17158	17158	13540
Adj. R-squared	0.938	0.986	0.933	0.961

Dependent variable: Log(Output). Standard errors (in parentheses) clustered by firm. Regressions include industry-year interaction dummies and LLM-year interaction dummies. The variable 'H workers' is the number of knowledgeable workers currently observed at non-HWFs. Column 1 is estimated on the sample of Medium-Wage-Firms (MWFs) and includes workers with recent experience at HWF and Low-Wage-Firms (LWFs). ' $\beta_{\tilde{H}}^{HWF} = \beta_{\tilde{N}}^{LWF}, pv$ ' is the p-value of the equality of coefficients of the variable 'Recent HWF exp' and the variable 'Recent LWF exp'. Column 2 reports within estimates. Column 3 adds the shares of managers, white collars, blue collars, females, and differently aged workers. Column 4 includes polynomial functions of capital, materials and number of employees in both t and t+1. This specification is in the spirit of the Akerberg, Caves, and Frazer (2008) approach.

Table A.9: Knowledgeable Workers and Productivity in non-HWFs, 1995-2001, alternative grouping of firms based on TFP

	(1)	(2)	(3)	(4)	(5)
	OLS	OP	LP	Inv-Cap Interactions t,t+1	Mat-Cap Interactions t,t+1

log(materials)	0.638 (0.003)	0.630 (0.004)		0.644 (0.007)	
log(employees)	0.142 (0.004)	0.125 (0.006)	0.136 (0.003)	0.112 (0.008)	0.128 (0.004)
H workers	0.019 (0.002)	0.022 (0.002)	0.023 (0.002)	0.021 (0.004)	0.017 (0.002)
Observations	16377	6225	16377	2712	12760
Adj. R-squared	0.940			0.942	0.945

I identify potential good firms as high-TFP firms. Specifically, I estimate firm effects from a specification in which the dependent variable is output, and I control for inputs. I identify good firms as those whose estimated firm fixed effects fall within the top third of all estimated firm effects. In this Table, H workers is the number of workers with experience at good (i.e. high-TFP) firms currently observed at non-good (non-high-TFP) firms.

Dependent variable: Log(Output). Standard errors (in parentheses) clustered by firm. Column 1 reports estimates using OLS. Column 2 implements the procedure in Olley and Pakes (1996). Column 3 implements the procedure in Levinsohn and Petrin (2003). Column 4 adds a third-degree polynomial function of log capital and log investment and the interaction of both functions in t and t+1. Column 5 includes the same controls as col. 5 but replaces log investment with log materials.

Table A.10: Knowledgeable Workers and Productivity in non-HWFs, Robustness to Different Specifications

	(1)	(2)	(3)	(4)	(5)
	Value Added	Share	Log	Input-Industry Interactions	Translog Functional Form
log(capital)	0.256 (0.007)	0.094 (0.005)	0.092 (0.005)	0.016 (0.028)	0.225 (0.028)
log(employees)	0.551 (0.010)	0.228 (0.006)	0.223 (0.006)	-0.064 (0.020)	0.378 (0.033)
H workers	0.079 (0.005)			0.026 (0.003)	0.009 (0.003)
log(materials)		0.585 (0.007)	0.583 (0.007)	0.255 (0.055)	-0.306 (0.035)
share of H workers		0.422 (0.131)			
log(H workers)			0.057 (0.010)		
No H workers			-0.034 (0.006)		
Observations	17116	17158	17158	17158	17158
Adj. R-squared	0.775	0.931	0.931	0.936	0.956

Log(Output) is the dependent variable in all columns excepts Column 1. In Column 1, Log(Value Added) is the dependent variable. Standard errors (in parentheses) clustered by firm. Regressions include industry-year interaction dummies and LLM-year interaction dummies. The variable 'H workers' is the number of knowledgeable workers currently observed at non-HWFs. The variable 'log(H workers)' is the logarithm of number of knowledgeable workers. The dummy 'No H workers' takes value 1 if the number of knowledgeable workers is equal to 0. Column 1 reports estimates with Log(Value Added) as dependent variable. Column 2 replaces the number of H workers with the share of H workers. Column 3 replaces the number of H workers with the log of H workers plus the dummy 'No H workers'. Column 4 allows the effect of each input to differ by two-digit industry level. Column 5 uses a translog functional form for inputs.

Table A.11: Knowledgeable Workers and Productivity in non-HWFs, Further Extensions, 1995-2001

	(1)	(2)	(3)	(4)	(5)
	Same/Diff Industry	Previous Occupation	Current Occupation	Continuous Measure	Lag
H from same Ind	0.035 (0.006)				
H from diff Ind	0.028 (0.004)				
H current higher-skilled occ.		0.042 (0.006)			
H current lower-skilled occ.		0.025 (0.004)			
H previous higher-skilled occ.			0.044 (0.006)		
H previous lower-skilled occ.			0.025 (0.004)		
Exposure				0.026 (0.013)	
Lag (H Workers)					0.024 (0.005)
$\beta_H^{same} = \beta_H^{diff}, pv$	0.232				
$\beta_H^{high} = \beta_H^{low}, pv$		0.013	0.006		
Observations	17158	17158	17158	17158	16265
Adj. R-squared	0.931	0.931	0.931	0.931	0.932

Dependent variable: Log(Output). All columns include log(capital), log(labor) and log(employees). Standard errors (in parentheses) clustered by firm. Column 1 differentiates between workers moving within the same industry and between industries. $\beta_H^{same} = \beta_H^{diff}, pv$ is the p-value of the equality of coefficients of the variable 'H from same Ind' and the variable 'H from diff Ind'. In Column 2 H is disaggregated into two groups based on the occupation at the previous employer (HWF). In Column 3 it is disaggregated based on the occupation at the current employer (non-HWF). $\beta_H^{high} = \beta_H^{low}, pv$ is the p-value of the equality of coefficients of the H workers in higher-skilled occupations and the H workers in lower-skilled occupations. In Column 4 I employ an alternative, continuous, measure of the receiving firm's exposure to knowledge, which exploits the differences between sending and receiving firms, thus extending the analysis above which has so far worked with a dummy indicating experience at a HWF (see text for details on the definition of this variable). In Column 5 the variable of interest is lagged by one year.

Table A.12: Knowledgeable Workers with experience in the same industry and Productivity in non-HWFs, 1995-2001

	(1)	(2)	(3)	(4)	(5)	(6)
	OLS	OP	LP	Inv-Cap	Inv-Mat	IV
				Interactions	Interactions	
H from same Ind	0.036 (0.006)	0.037 (0.008)	0.031 (0.005)	0.022 (0.012)	0.026 (0.006)	0.121 (0.062)
Observations	17158	6635	17158	2963	13540	17158
Adj. R-squared	0.931			0.940	0.952	0.921
Fstat, instrum., 1st stage						27.22

Dependent variable: Log(Output). All columns include log(capital), log(labor) and log(employees). Standard errors (in parentheses) clustered by firm. The variable 'H workers same Ind' is the number of workers with HWF experience in the same industry currently observed at non-HWFs. Column 1 reports estimates from the baseline specification. Column 2 implements the procedure in Olley and Pakes (1996). Column 3 implements the procedure in Levinsohn and Petrin (2003). Column 4 adds a third-degree polynomial function of log capital and log investment and the interaction of both functions in t and t+1. Column 5 includes the same controls as col. 5 but replaces log investment with log materials. Column 6 reports IV estimates using the lagged number of downsizing local good firms in the same 4-digit industry. It includes an indicator of the importance of local demand, namely a dummy taking value 1 if the 4-digit industry produces goods that are not widely traded outside the LLM. It also controls for an index of industry localization, namely the ratio between the number of firms in Veneto and total Italian firms in a given 4-digit industry.

Table A.13: Number of local HWFs and Productivity, Estimates, 1995-2001

	(1)	(2)	(3)
	OLS	System GMM	Two-step System GMM

AR(3)z		1.954	1.969
AR(4)z		-1.147	-1.169
HansPv		0.874	0.874
Adj. R-squared	0.931		

Dependent variable: Log(Output). Standard errors (in parentheses) clustered by LLM. Regressions include year dummies. Column 1 reports OLS estimates. Column 2 reports System GMM estimates. Column 3 reports two-step System GMM estimates, using Windmeijer-corrected standard errors. In Column 2 and 3 the variables 'Local HWFs in same industry' and 'Local non-HWFs in same industry' are treated as endogenous. AR(1)z, AR(2)z, AR(3)z, AR(4)z: Arelanno and Bond (1999) test of first, second, third and fourth order serial correlation, distributed as N(0,1). HansPv: p-value of Hansen test of overidentifying restrictions. Only the shortest allowable lagged is used as instrument. $\beta_{HWFs} = \beta_{non-HWFs,pv}$ is the p-value of the equality of coefficients of the variable 'Local HWFs in same industry' and the variable 'Local non-HWFs in same industry'.
